THE EDUCATION BILL

IN several recent issues (NATURE, 152, 393, 427, 455, 483, 517, 545) we have dealt with the White Paper which heralded the Education Bill, beginning with a general survey, and proceeding to special aspects which in our judgment most nearly touch the real problems of education in Great Britain. We now have before us the long-awaited Education Bill, with the accompanying Explanatory Memorandum*. Let it be said at once that the Bill goes far to meet the criticism and the suggestions which we, like many others, have ventured to express.

First, however, comes an unanticipated change which happens to be of cardinal importance. At present there is no real Ministry of Education. The functions of the President of the Board of Education are vaguely defined as "the superintendence of matters relating to education in England and Wales", the result being that, however convinced the President may be that a certain step is desirable, he may have no power to act, but may only be able to offer advice and bestow his blessing. The Bill proposes a radical change. There is to be no change of name. We shall still have a Board of Education and a President (with rank of Minister), but the latter will be equipped with powers which mean that we shall have something akin to a Ministry of Education, just as surely as we have a Ministry of Works or of Labour. Any fear of over-centralization of power is allayed by the importance of the functions allotted to the local authorities. The addition of Central Advisory Councils for England and Wales respectively, charged with the duty of advising the Minister on "such matters of educational theory and practice as they think fit", is a signal that the Board is meant to be a great deal more than an administrative machine.

Broadly speaking, the White Paper was received with a chorus of approval, both in Parliament and in the country, at least with regard to its purely educational proposals. Perhaps the most widely expressed sense of disappointment related to the "exceeding lack of speed" implied in the Paper. The Bill meets this criticism by taking the bold step of fixing April 1, 1945, as the date for raising the school-leaving age to fifteen, the President being empowered, however, for a period limited to two years, to retain the age of fourteen where it is impossible to provide the necessary buildings and teachers in time. The same date is fixed for the coming into operation of provisions regarding health and physical training, the modification of the dual system, religious education, and the adjustment of the present system of local administration. The date for raising the leaving age to sixteen is to be fixed by Order in Council, as soon as the Minister deems it practicable. So also will the date on which it will become the duty of local authorities to secure the provision of the necessary facilities for the compulsory part-time education of young persons.

Another of the rather bitter cries evoked by the

* A Bill to Reform the Law relating to Education in England and Wales. Pp. xii+98. 1s. 6d. net. Education Bill: Explanatory Memorandum by the President of the Board of Education. (Cmd. 6492.) Pp. 14. 3d. net. (London: H.M. Stationery Office, 1943.)

White Paper is met by a financial allocation for technical and adult education more than three times as large as that proposed in the Paper.

The duty of local authorities to secure adequate provision of primary and secondary schools, and not merely, as at present, to keep efficient the elementary schools in their areas, is to include the duty of providing nursery schools. The provision of these schools was left as a power only by the Act of 1918, and, as the event has shown, the power has been little used, notwithstanding the acknowledged necessity for these schools from the point of view of social amelioration. In this respect, as in many others, the assent of Parliament will amount to an intimation to local authorities that the nation has made up its mind on the subject.

The other failure to carry out the intention of the Act of 1918 was that which related to the ill-fated day continuation schools, opposed by the less far-seeing kind of employer, and scarcely welcomed by boys and girls, who had no desire to be sent to school again. The Bill provides for part-time continued education, not in day continuation schools, but in young people's colleges. The change of name, though perhaps sounding slightly pretentious, is exactly in the right direction, because it implies for the young person an entirely fresh start, an increased freedom from the restraints necessary during childhood, and a new opportunity of practising self-mastery. Attendance is to be obligatory for all young persons up to the age of eighteen who are not receiving full-time education. The arrangement of times is left to the local authority, but otherwise part-time education will be similarly organized throughout England and Wales.

An outstanding feature of the Bill, representing a considerable advance upon the White Paper, is that the way is opened for better provision for physically or mentally handicapped children. Hitherto the duty of ascertainment by the local authority has been restricted to defective and epileptic children. It is now extended to all types of children needing special educational treatment, including those who have come to be known as maladjusted. Also, the requirement that a handicapped child must be certified as defective before he can receive special treatment is removed. It will be the duty of the local authorities to provide special schools for the seriously handicapped, and special treatment for the less serious cases. From our point of view there are in this subject two points of compelling interest: first, that compassion towards those who are not to be winners in life's race is one of the fine things in a democracy, and, secondly, that the remedial treatment now possible is the result of applying scientific methods. In that connexion we may mention also the more general power which the Bill confers on a local education authority to "make such provision for conducting or assisting the conduct of research as appears to the authority to be desirable for the purpose of improving the educational facilities provided for their area". In this forward step one sees the promise of the substitution of scientific method for empiricism and guesswork. A similar blend of humanity and efficiency is seen in the powers conferred upon local authorities with regard to medical inspection and treatment, the provision of milk and meals, of boots and clothing—the parent to pay according to his means or lack thereof.

One result of current discussions about public schools has been to bring to the front the general question of boarding-schools for children of the unprivileged, when that arrangement seems desirable. In response to the arguments brought forward, the Bill provides that a local authority may set up a boarding school "for pupils whose education renders their residence away from home desirable, either because their parents desire that they should be educated as boarders or by reason of the remoteness of their homes or of other circumstances". Here it may be mentioned that the Bill maintains a stony silence as to the public schools, notwithstanding the lively discussions which have occurred lately, and the numerous letters that have appeared in the correspondence columns of *The Times* and of other newspapers. It is scarcely to be expected that the same silence will be maintained during the passage of the Bill through Parliament.

As to the coming Parliamentary debate, it is devoutly to be hoped that those prophets are wrong who foresee that most of it will be taken up by lengthy and perhaps acrimonious tirades about the dual system of control and the cognate question of religious education. Let anyone examine the records of the debates on the Bill of 1870, and let him cross out the parts relating to the denominational disputes, and he will find that there is not much left. We do not want, and we are sure that the general public does not want, a repetition of that vain war of words. Apart from 'the secular solution', of which we used to hear so much, but for which the general public is not prepared, there is only one way—the way of compromise, of give and take, which is essential in a democracy, and in which the British are said to excel. We trust that almost the last word has been said by way of patient and sincere and honestly sought compromise on these questions, it being known beforehand that as no one can get the whole of what he wants, so everyone will get some of what he wants. Thus the energies of Parliament would be available for educational matters which come nearer to the business and bosoms alike of parents and teachers and administrators.

One of those matters we account of vital importance is the development of a real democracy, in which every young citizen gets the opportunity to which he is entitled by his abilities. The White Paper proposed a division of secondary education into three types, to which there should correspond grammar schools, technical schools, and modern schools. The many virtues of the existing secondary schools, which inherited the traditions of the old grammar schools, were fully recognized, as also their gradual failure to meet the needs of able children who ought never to have been attracted into a type of school predominantly academic in its outlook. For them it was proposed that the secondary technical school should be developed, taking its start from the existing

junior technical schools and technical colleges. By many critics these proposals have been denounced, the grammar school as lopsidedly bookish, and the technical school as unlikely to engender that interest in the humanities which is one of the hall-marks of the well-educated man, and without which science cannot adequately express itself.

But the chief anxiety of some of the most experienced critics has been about the proposed modern schools, which must be *the schools of the masses*. It is perfectly true that the intention is to bring these schools up to the standard of the grammar schools in point of buildings, equipment, staff, size of classes, 'amenities', and so on. But just as the existing secondary schools inherited the traditions of the old grammar schools, so these senior or modern schools will inherit the traditions of the old elementary schools, into the details of which we need not enter. The staunch adherents of the democratic ideal must now, and for years to come, insist upon the fair promises embodied in the Bill being faithfully carried out, and they may have a hard struggle. The Bill does not lay down a three-fold division of the new secondary system, but leaves the local authorities to propose their plans of development. In other words, the Bill leaves room for experiment, even in the direction of the multilateral organization of American high schools. It is to be hoped that this ordered freedom to experiment will be benevolently regarded by the Minister, and will lead to valuable results. The general ends in view would be furthered if it could be arranged that a teacher's remuneration should depend upon his qualifications and experience, and not upon the kind of school in which he teaches. It would be a happy day for British education if some of the ablest and most enterprising members of the teaching profession could feel quite free to teach in any kind of school, without forfeiting one jot or tittle of their professional rights and privileges.

SCIENTIFIC PERSONNEL IN INDUSTRY

No one who has followed the recent discussions and reports on industrial and scientific research can have failed to notice the emphasis which has been placed on the research worker himself, and on the importance of ensuring that the conditions of service are such as to attract men of the highest ability and to retain their keenness and loyalty.

There is no more welcome passage in the report* of the Industrial Research Committee of the Federation of British Industries on "Industry and Research" than that which deals with the scientific worker in industry. It is clearly recognized that on the proper position of the research worker within the organization employing him depends to some extent the power of industry to attract the best scientific brains to its service. Nevertheless, the report finds it necessary to point out that the best results can only be obtained when the research staff is taken fully into the confidence of the management and given a definite standing in the hierarchy of the organization. The research worker cannot be expected to perform his duties efficiently unless he has at his disposal all relevant information which is in the possession of the organization of which he is a member.

The report goes on to acknowledge that publication of the scientific aspects of his work is a legitimate ambition of every scientific worker, and that such ambitions are not as a rule inconsistent with the interests of firms engaged in competitive industry; on the contrary, such publication increases the prestige of the firm concerned. Again, research and development can generally only be efficient on the basis of co-ordinated team-work, with a team properly balanced as between the leader and his various grades of assistants. The personality of the leader is of the greatest importance; a successful leader is one who appreciates the ambitions and capabilities of the separate members of his team and has the gift of communicating to them his own enthusiasm and a full appreciation of the objects the team is seeking to achieve; above all, he must be able to make discriminating acknowledgment of the contribution of each member of the team to the common objective. Sir Lawrence Bragg also has emphasized the need for more inspired leaders in industrial research, and suggested that we should divert more of the national genius to industrial research by recruiting potential leaders of this kind into industry, where they should be coached for positions of high responsibility. In his view the Central (Scientific and Technical) Register could be used to locate and recruit such men.

It may be encouraging to find such statements in the report of the Federation of British Industries, but neither here nor in the comments on the benefit that has flowed from the transfer of research workers having the requisite personal qualifications to commercial, administrative and other branches of activity is there the note of conviction that makes them something more than platitudes. The more an organization is staffed on all its sides by persons having an appreciation of science and research, the more progressive and adaptable to changing circumstances it is likely to be. Little benefit indeed will be derived from increasing the numbers of those engaged on research if trained minds are not more fully employed in other branches of industry, and the general scientific outlook of industry must be raised if the understanding and application of scientific inventions, discoveries and developments by industrial firms are to be increased.

We miss in the report the urgent sense of the primary importance of seeing that scientific workers of the highest quality are first attracted to industry and then set to work under conditions which give the utmost play and stimulus to their creative powers. That consciousness clearly inspired the motion tabled in November in the House of Commons by a large number of members of all parties, asking for wider State support in planning future developments for research, teaching and higher learning as a whole, including provision for a far greater number of persons highly trained in science and technology. Again, the

* Federation of British Industries. Industry and Research: Report of the F.B.I. Industrial Research Committee. Pp. 24. (London: Federation of British Industries.)

report appears to ignore all those fundamental questions of the organization of research in relation to the personal factor which are vital and which were discussed by Dr. Alan Gregg, director for the medical sciences at the Rockefeller Foundation, in his Terry Lectures, "The Furtherance of Medical Research". Standards of remuneration must indeed be high enough to attract and to hold men of outstanding ability. They should also be such as to ensure that preoccupation with proper provision for their families does not intrude unduly on the research worker. Lord Bledisloe has rightly stressed the importance of mental concentration, quietude of mind and freedom from domestic anxieties if the research worker is to give of his best.

While, however, certain minimum standards are essential, the vital factor is the maintenance of the highest possible professional standards, the clash of mind with mind especially on the borderlands of sciences, the correction by every possible means of the ingrained evils of specialization. Refresher courses may do something to help, as may the transfer of staff within and without industry, for Lord McGowan was profoundly right in urging that scientific workers should not allow the lavish provision of scientific literature in the industrial library serving the research department of a large firm to lead them to refrain from joining professional societies and attending scientific meetings and participating in the discussions. The warning is timely and is a reminder of one respect at least in which the maintenance of the highest standards of research is a matter for the scientific worker himself.

A more generous policy in publishing the results of industrial research, as advocated by Lord McGowan and Dr. P. Dunsheath, and by Mr. Samuel Courtauld in a recent article in *The Times*, would undoubtedly have a vitalizing effect in this respect, and its indirect consequences in stimulating discussion and professional association might be out of all proportion to the direct value of interchange of information to which Lord McGowan referred, in such matters as fuel economy, heat transfer, corrosion and the design and performance of plant. Moreover, the question of the suitability of the present patent law system of Great Britain in this respect has been raised too often for it to be dismissed quite so cursorily as it was by Lord McGowan. It was raised most explicitly by Dr. Dunsheath, and Mr. Courtauld returns to the point when he urges that it is open to question whether the Government should assist research by direct contribution, or by remitting taxation, while allowing the fruits of that research to be withheld from the nation by means of patents not fully and efficiently worked.

On the other hand, as Mr. Courtauld recognizes, publication has its own difficulties. Government-maintained institutions must have a free hand, and fundamental research will be one of their main functions. The publication of fundamental discoveries must be subjected to the decision of a very high and impartial tribunal, always with an eye on possible foreign competitors. Existing interests must not be allowed to retard publication beyond the point where these coincide with public policy.

Mr. Courtauld is here entering on the difficult question of social adjustment. It may indeed be right and for the advantage of the community that a particular industry should be closed down, because of other benefits arising from the discovery or invention responsible. It may be questioned, however, whether this is relevant to the question of publication: if we make sure that such decisions affecting the fate of an industry are not determined by private interests but by public policy, which takes account of the displacements and adjustments involved, there seems to be no intrinsic reason for barring publication. Moreover, Mr. Courtauld's remarks in this connexion appear to threaten that full and free interchange of fundamental knowledge across national frontiers which is essential to scientific advance and the defence of which is one main concern of men of science in the present War.

Mr. Courtauld's challenge to the old-fashioned love of secrecy is, however, unmistakable, and many will hold with him that it has brought more harm than good to the manufacturer. Undoubtedly it undermines the relations between the research staff and management and hinders the establishment of that full confidence and understanding which play so important a part in stimulating research and bringing its conduct to the highest efficiency. The more liberal policy pursued in the United States may well be an important factor in some of the industrial achievements in that country. Mr. Courtauld is unquestionably right in holding that the maximum degree of publication and co-operation consistent with reasonable safeguards against abuse will accelerate the healthy growth of every industry based upon applied science.

It is clear, therefore, that the reports to which we have referred are far from exhausting this question of establishing the conditions under which research can be carried on with the greatest advantage. Fundamentally, we still know relatively little of the biology of invention or discovery, but in the organization and maintenance of research we are often very far from applying all the knowledge at our disposal, and these reports afford welcome evidence that this is realized and that further attempts are being made in this direction. Moreover, they indicate that industry is coming to understand that more could be done even before the scientific man enters the service of industry; the greater interest being taken by industry in technical education, and the recommendations for the more general provision of funds for the creation of fellowships, bursaries or the like at universities and technical schools and colleges for junior personnel in the industry who show an aptitude for a scientific career, are encouraging signs.

How great is the need in this respect is shown in an interim report of the British Association Committee on Post-war University Education dealing with university entrance scholarships in England and Wales*. It is not merely that the supply of scholar-

* British Association. Committee on Post-War University Education. Report on University Entrance Scholarships in England and Wales. Pp. 8. (London: Burlington House, 1943.) 6*d*.

ships is inadequate, and that in particular if adult education becomes much more widespread there should be an increase in the number of university entrance scholarships offered without an upper age limit; the methods of selection themselves receive severe criticism. The Committee holds that the present system harms a large majority of the scholarship candidates, subjecting them to conditions which place a premium on absorptive processes; it ruins altogether a small percentage of the candidates and misses some first-rate material.

The attention which industry is already giving to qualities other than purely intellectual attainments in selecting its recruits should lead it to mark very carefully what this report says about the deleterious effect of the present scholarship system upon the social life of the school, and particularly the untoward effects, on boys much more worth while than many of the successful candidates, of concentrating undue attention upon the more brilliant minority. The Committee gives a strong warning as to the necessity of carrying selection a step further. If we are to make the best of our youth, we need to get into our universities more of the leaders of the coming generation as well as the intellectual elite. We need, besides scholars of outstanding intellectual quality, men and women who combine good intelligence with qualities of character and personality, so as to be the natural leaders in other fields than those of science and learning.

This plea for character and leadership is one to which assuredly industry should not turn a deaf ear. The plea that the assessment of deep scholarship should always be accompanied by the assessment of character, and that the latter for most assisted students should carry equal weight in considering their worthiness to be admitted to a university, has strong claims on the support of industry, which is already beginning to assess its recruits by some such standards. Industry could indeed, if it chose, lend powerful support in overcoming the obstacles to the appropriate remodelling of the scholarship examinations involved in the success of any such reform, and the experience of the interview it already possesses might well be drawn upon in establishing the more effective use of the interview, with the appropriate safeguards, in examinations for entrance scholarships to universities. With that, and with real weight attached to the candidate's school record, to his English essay and to his general papers as well as to his intellectual promise in his own special branch of study, we may well find such an improvement in the quality of the recruits industry draws from the universities as will react profoundly not only on the quality of industrial research and on the application of advances in science, but also on the whole standard of industrial leadership and management. What is essential is that industry should show even more of the spirit of co-operation and open-mindedness which these reports and papers display, and tackle with more determination and thoroughness those fundamental questions of the organization and the management of research over which the Federation of British Industries tends to pass too lightly.

HISTORY OF ELEPHANTS

Proboscidea

A Monograph on the Discovery, Evolution, Migration and Extinction of the Mastodonts and Elephants of the World. By Prof. Henry Fairfield Osborn. Edited by Mabel Rice Percy. (Published on the J. Pierpont Morgan Fund by the Trustees of the American Museum of Natural History.) Vol. 2: Stegodontoidea, Elephantoidea. Pp. xxvii+805–1176+19 plates. (New York: American Museum Press, 1942.) 20 dollars.

THE Proboscidea are such very large animals that their fossil bones and teeth attracted attention in the far distant past, but only in 1698 did W. E. Tentzelius prove that giant bones found in a sandpit at Tonna in Thuringia were those of an elephant, and were not "minerale fossile, sed animale petrifactum". Before 1800 Blumenbach and Cuvier showed that some fossil elephant teeth belonged to species and genera no longer living.

Hugh Falconer, who died with much of his work unpublished in 1866, brilliantly ended another phase of the discovery and interpretation of fossil elephants by showing that they could be arranged in a morphological series providing every intermediate stage of tooth structure between a primitive mastodon and the most advanced true elephant, the mammoth. With the general acceptance of the theory of organic evolution, it was at once realized that Falconer's morphological series was in a wide sense an evolutionary one, but little real advance was made until, in 1904, C. W. Andrews found in Egypt two evolutionary stages earlier than any then known, which fitted into place before the beginning of Falconer's series; and went on to give a convincing explanation of "how the elephant got his trunk".

Dr. Andrews was well aware that the series of forms he used was not a real phytogenetic series, that Moeritherium, its earliest term, was not actually the ancestor of its successor Palæomastodon, and similarly for the other stages. But he realized, for example, that *Trilophodon angustidens* was representative of all other Lower Miocene mastodons in its characteristic greatly elongated lower jaw, and that no form with the shortened, but still long, lower jaw of his next stage, *Tetralophodon longirostris*, had been found in rocks older than the Upper Miocene.

In his mind, the important fact was the time of first appearance of each stage of evolutionary advance, the trend of evolution being established on that basis without any attempt (which would then have been impossible) to sort out independent genetic lines among the whole material of fossil Proboscidea (cf. *Phil. Trans.*, B, **196**, 101).

In 1907, H. F. Osborn began to bring together in the American Museum of Natural History materials which would enable him to apply to Proboscidea those methods of analysis of structural details which he had already conceived and used in the study of Rhinoceroses and Titanotheres. In 1920, he began that detailed work, which continued until his death in 1935. At that time, 1,240 figures, each often containing many individual drawings or photographs, had been prepared for publication, much of the text was complete and some of it in type, and an immense accumulation of notes existed. The piety of Miss Mabel Rice Percy and others has enabled the whole to be published in two magnificent volumes, of which the first was reviewed in NATURE (**138**, 860) on its

publication in 1936, while the second, devoted to the elephants and their immediate predecessors, appeared in 1942.

The circumstances of its publication have made this monograph exceedingly difficult to read and understand, for early interpretations crop out among later views, especially with respect to the age of Asiatic forms, and there is much repetition. The present volume, however, contains an invaluable and most judicious chapter by Dr. E. H. Colbert on the "Geologic Succession of the Proboscidea", which should be read as an introduction by anyone studying the whole; and a modern interpretation in footnotes corrects earlier statements of the age of each species.

None the less it is a difficult work, only to be understood by persons who have a familiarity with actual fossils and the earlier works which have been written about them. But it is invaluable, one of the greatest of all palæontological works, because it brings together an immense material, illustrates it fully by most accurate and intelligible figures, and applies to it a minute analysis of structures and a mode of interpretation which is comprehensible and logical.

According to Osborn, the actual history of the elephants is as follows. In lower and middle Miocene times there existed mastodons which can be distinguished from all others because the transverse crests on their first and second molar teeth, three in number, are separated by valleys which are not blocked by subsidiary cusps. They have long lower jaws, in common with all other mastodons of the same times. This group can be divided into three; one, distinguished by the fact that each crest on the molars is cleft into two halves, leads on to the 'American' mastodon. The second group lacks the cleft which splits the molar crests, but each crest bears four or five subsidiary cusps on its summit. The upper tusks lack an enamel belt. The third group, Turicius, is distinguished from the second by the presence of a ridge descending into the valley on the posterior surface of one end of each molar crest, and of an enamel band on the upper tusks. Each of these three groups can be followed to Middle Pliocene or later times, the lower jaw shortening and the crests becoming higher, though not more numerous, in accordance with the evolutionary trends established by Falconer and Andrews.

The third group, Turicius, is held by Osborn to include in all probability the ancestors of the true elephants. Before it had died out there appears a new genus, Stegolophodon, the oldest member of which, from the base of the Pliocene, differs from Turicius in having four crests instead of three on its first and second molars, which have very low and swollen crests with some six conelets on their summits, but retains the enamel band on the upper tusk. This genus lives on to Lower Pleistocene times.

In Middle Pliocene times appeared the genus Stegodon, with six or seven crests on its first and second molars, each bearing some nine subsidiary cusps on its summit, and having the valleys partially filled by cement. Stegodon lived on to Middle or Upper Pleistocene times, the series following the normal evolutionary course, so that the second molar of the last form has nine very high crests and the third fifteen crests.

But in Lower Pleistocene times appears the first true elephant, *Archidiskodon planifrons*, with nine or ten crests on its second and twelve on its third molars, each crest having six to ten conelets on its summit. The real difference between this animal and a Stegodon with a similar number of crests is in the fact that in it the crests have become plates with parallel sides, while in Stegodon they are wedge-shaped in section. But the very primitive South African *A. proplanifrons* and the very advanced Japanese *Stegodon auroræ* bridge the gap.

From *Archidiskodon planifrons* arose a series of elephants, with skulls of comparable shapes, in which the numbers of plates in the teeth increase to eighteen in the third upper and twenty in the third lower molars. The teeth become immensely deep, a plate measuring so much as 24 cm., compared with a maximum of 6 cm. in *A. proplanifrons*.

The final term of this series, *A. imperator*, with its varieties, reached the height of thirteen feet, and its tusks, much curved and with their inwardly directed tips crossing, may reach the astonishing length of sixteen feet. This line survived to Upper Pleistocene times. Parallel to it, and also found both in Europe and North America, are two other lines of descent, one leading to the Arctic mammoth, the other including the European *Parelephas trogontherii* and many American species.

The three groups differ markedly in the shape of their skulls, but it is often difficult to distinguish isolated teeth with certainty. The Parelephas line ranges from Lower to Upper Pleistocene, the plates of the last molar increasing in number from fourteen to thirty and the heights from 15 cm. to 24 cm. The mammoth line can also be followed from Lower to Upper Pleistocene times, the ridges increasing from nineteen to twenty-seven, while the height changes little. It can be distinguished by its high, short, pointed skull, in contrast to the rounded cranium of Parelephas.

Osborn having in this way worked out three lines of descent (the lineages of invertebrate palæontologists), which he calls sub-families, among the very close allies of the mammoths, proceeds to deal similarly with other elephants.

One family includes those elephants in which the bases of the tusks diverge widely. It also is divided into three sub-families; one of which, badly known, ends in the living African elephant, another includes a giant Indian Pleistocene form and the pigmies of the Mediterranean Islands, while the third is erected to contain the straight-tusked elephants of the European Pleistocene. Each sub-family shows some part of an evolutionary story of tooth development paralleling that of the mammoths.

Finally, a third family includes the living Indian elephants, the ancestry of which is unknown, and two allied forms from the Middle Pleistocene of the Sivaliks.

Prof. Osborn has thus made the first attempt to work out in detail the phylogeny of the 330 extinct species of Proboscidea which he regards as well founded. He has done so by the systematic search for criteria for the discrimination of closely similar animals which are members of stocks pursuing parallel evolutionary courses, and finally recognized twenty-one independent lines of this kind which may be followed for longer or shorter periods.

The most important conclusions which follow from Prof. Osborn's work seem to be as follow:

(*a*) The evolution of the Proboscidea is polyphyletic, stocks which separate from one another at any time afterwards pursuing parallel evolutionary courses.

(*b*) Comparatively inconspicuous features of the

teeth may persist unaltered, or little changed, for long periods.

(c) The evolution of such characters as the number of crests on a molar tooth is independent of the evolution of other characters of the tooth, such as the height of the crest.

(d) New progressive stocks arise from a point only a little above the base of the parent stock.

(e) Two stocks which separate from one another may differ very greatly indeed in the rate at which evolutionary changes take place in them.

(f) Progressive stock and parent stock may continue to live side by side, so that their remains may be buried in the same bed.

(g) The evolution of the Proboscidea has been a rapid process in comparison with that of horses or camels.

(h) The extinction of sub-families of Proboscidea occurred at all geological periods, twelve sub-families living on into Pleistocene times, four—two mastodons in America and two elephants—surviving to Recent time, two only still living.

The history of the elephants has thus been more completely illustrated than that of any other mammalian order, because in other cases no man has had at his command resources which enabled him to bring together in one place so much material, to have this material prepared and illustrated, to allot special points to able collaborators for further investigation, to have published papers sought for, translated and abstracted, and the notes of many years work kept in order by a most able secretary. If these conditions could be met, it is probable that many other mammalian orders and sub-orders would yield the details of an even more complete story, now existing fragmentarily in scattered publications.

It is perhaps useful, because of its great importance to archæologists, to direct attention to the fact that a South American mastodon, *Cuvieronius postremus*, has been found in Ecuador in association with human artefacts which are only 1,600–1,800 years old. D. M. S. WATSON.

THE TRAINING OF A REGIONAL PLANNER

Regional Planning

An Outline of the Scientific Data relating to Planning in Great Britain. By L. B. Escritt. Pp. 264. (London: George Allen and Unwin, Ltd., 1943.) 12s. 6d. net.

THE author of this handbook considers that regional planning is "a real study of growing importance", and that in the training of those who will undertake such planning more studies are involved than engineering and architecture. He shows the relevance of geology, the study of soils and soil surveys, of agriculture and land utilization, and a wide range of other subjects. In the space of little more than 250 pages, he has endeavoured to demonstrate the ways in which a knowledge of these subjects can be applied to problems of regional planning. He has written, generally, for the uninitiated, and has not assumed much preliminary training in any of these subjects.

The book "is addressed in particular to town planning, engineering and architectural students", but it is hoped that it will also be of interest to local government administrative officers. It may perhaps be hoped that no students of regional planning will confine their knowledge, for example, of geology, to the brief summary given in this volume: the useful lists of references to general literature and to publications specially dealing with planning will be a stimulus to much wider reading. But apart from the student aiming at professional qualifications, it may be suggested that many non-technical members of planning committees, reconstruction associations and similar bodies will find much in this volume to interest them.

An introductory chapter is followed by an attractive account of regional surveying, a subject in which Mr. Escritt evidently takes a keen interest. He makes frequent reference to the "Atlas of Croydon" and to the regional survey on which it was based: several illustrations reproduced here have been derived from that source. He strongly urges the need of such surveys as a basis for post-war planning.

In the fourth chapter Mr. Escritt discusses the education of the planner. He points out that the Scott Report expressed some dissatisfaction with the training of planners, and put forward the view that many employed as town planners are inadequately trained in the broader aspects of their work.

Mr. Escritt makes interesting comments on the syllabus prepared for the Town Planning Institute examination, and notes that at present "all universities that provide courses of study in town planning treat planning as a section of architecture, or include it as part of the work of an architectural department". He puts forward tentatively a scheme of study for those who enter the profession of planner via the universities. He suggests that this course should include work in geology, agriculture (including soil survey and forestry), economics, engineering (with some mathematics, physics, surveying, municipal engineering), architecture, regional surveying and planning. Obviously, a course designed to cover such a wide range of studies would need to be of longer duration than most degree courses, while the provision of a unified scheme of instruction in such a field would present problems of great difficulty. It may be wondered whether the training of regional planners would not be more satisfactorily approached by way of certain existing degree courses, with subsequent postgraduate instruction in those subjects which are not represented in the curriculum for the degree. Certain people would thus approach the problem with a training in engineering or architecture, others with a more general background of science or geography. For some types of regional planning it is likely that an honours course in geography, including surveying and some geology, would provide a better training in the broader aspects of the problem. Indeed, many will think that it is preferable for undergraduates to follow such courses before embarking on vocational training. If we are to have a body of professional planners, it may be most desirable to give only sufficient technical training to enable them to know which experts should be consulted.

In subsequent sections the author deals with "The Earth and its Products" (geology, soil, agriculture), "The Water Cycle" (drainage, water supply, sewerage), "The Town", and "Transport". Much ground has been covered, and Mr. Escritt has taken advice from a long list of specialists in order to make his work authoritative. As a small detail, a question may be asked regarding the use of the word 'hachure' on pages 48 and 50, which is not in accordance with the familiar practice in Great Britain.

A. E. TRUEMAN.

Formalization of Logic

By Prof. Rudolf Carnap. (Studies in Semantics, Vol. 2.) Pp. xviii+159. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1943.) 16*s.* 6*d.* net.

THE starting-point of Prof. Carnap's work is the distinction between two aspects or tendencies in logic. On one hand, there is the tendency to emphasize form, the logical structure of sentences and deductions, relations between signs in abstraction from their meaning: this is Hilbert and Bernays' *Beweistheorie*, Carnap's *syntax*. In contradistinction to it is the emphasis on meaning, interpretation, relations of entailment and compatibility as based on meaning, the distinction between necessary and contingent truth, etc.: this is *semantics*, and corresponds generally to Hilbert and Bernays' *mengentheoretische Logik*. Prof. Carnap is planning a series of studies on semantics, of which the volume under review is the second (the first being an "Introduction to Semantics"); it deals with the application of his methods to a criticism of the formalization of logic, that is, its representation by a formal system or calculus. The problem is to determine to what extent the logical calculi that have been constructed hitherto have actually effected the task of formalizing logic in such a way that the principal logical signs can be interpreted only in terms of the accepted logic of meaning; a question which the author answers in the negative. He shows, however, that a full formalization of propositional logic, and also of the logic of functions, can be effected by making use of new basic concepts, the most important step being the introduction of *junctives*, that is, of sentential classes in conjunctive and in disjunctive conception.

The book is an important contribution to the development of its subject.

Mathematical Statistics

By S. S. Wilks. Pp. xi+284. (Princeton, N.J.: Princeton University Press; London: Oxford University Press, 1943.) 25*s.* net.

IN the preface Dr. Wilks makes the remark, "If and when the present notes are revised and issued in a permanent form", which suggests that the author does not need reminding of the disadvantages of giving his work to the world in a paper-covered volume of litho-printed typescript. The reviewer has certainly found this format uncomfortable.

As to substance, it is clear that Dr. Wilks has industriously gathered much material from the periodical literature, rewritten it in a consistent, if austere, mathematical notation, and thrown overboard as superfluous almost all discussion of relevance and applicability. Whatever value the course of lectures on which it is based may have to the mathematical students who take them, it seems to give no insight into *why* any particular problem should be propounded, or as to the function of mathematical reasoning in improving statistical methods. Time after time a perfectly competent, though perhaps arid, section closes with a note of finality, without a hint of the wider horizons which might have been disclosed.

The book as it stands may well be useful to some, who occasionally need to refer to a careful and precise statement on some special point. They will not find it elaborated, or exemplified; and may well be disappointed, on the purely mathematical side, by the author's pedestrian style, for the development of mathematical statistics has not really been poor in those flashes of originality and penetration which mathematicians sometimes call 'artifices'. Dr. Wilks should not disdain to reproduce such work, for, like all good artistry, it gives much pleasure, without detriment to practical aims. R. A. F.

Oddities of Natural History

By Eric Parker. Pp. 228+8 plates. (London: Seeley, Service and Co., Ltd., 1943.) 12*s.* 6*d.* net.

READERS of the *Field* will be familiar with the kind of letters that find their way into the correspondence column of that journal. This column serves as a sorting-house for the unusual incidents and observations which are little known in the animal kingdom and for which we are deeply indebted to so many 'amateur' naturalists. In order that the more significant of these observations should be available in readily accessible form, Mr. Eric Parker has made an exhaustive examination into past issues of the *Field* over many years, and his collected findings are set out in this book. It will be of most value to those actual or would-be correspondents to the *Field* whose propensities enable them to interpret the behaviour of animals in terms of human sentiment and emotions. They will read the book with avidity. Naturalists who find the anthropomorphic and teleological assumptions a deflexion from rational objectivity will find much to irritate them. Parker's approach is in direct contrast to that of the writer whose recent book on the life of the robin showed how it is possible to maintain the strictest regard for exact observation and interpretation without in any way concealing one's love for the subject being studied. T. H. H.

A Star Atlas and Reference Handbook (Epoch 1950)

For Students and Amateurs. By Arthur P. Norton; the Reference Handbook by J. Gall Inglis and A. P. Norton. Ninth Edition. Pp. xvi+90. (London and Edinburgh: Gall and Inglis, 1943.) 15*s.* net.

THE first edition of this work appeared in 1910, and this latest edition—the ninth—contains a number of alterations to bring it more up to date. Stars from the Revised Harvard Photometry down to magnitude 6·35 have been charted, and all nebulæ, except those of Messier and those classed by Herschel, have received the N.G.C. numbers. Small circles are used to indicate all variable stars which attain the sixth or seventh magnitude at their maximum brightness. The recommendation of the International Astronomical Union regarding the galactic equator and poles has been adopted, so that these differ a little from those shown in the maps of the earlier editions. In the earlier maps, limited abbreviation lists were printed in the margins, and these have been replaced by a complete list occupying a page, preceding the charts.

In addition to the value of the work as a star atlas, it contains most useful and authoritative information on star nomenclature; astronomical terms; the galaxy and the stars; spectroscopy; the sun, moon, and planets; the care and use of the telescope. It is remarkable that so much reliable detail has been condensed into a little more than fifty pages, and the provision of an index at the beginning of the book enables one to turn immediately to the page which supplies the necessary information. An astronomer's library is incomplete without a copy of this valuable work.

DICHROISM

By Dr. W. D. WRIGHT

Imperial College of Science and Technology, London

"Will all great Neptune's ocean wash this blood
Clean from my hand? No, this my hand will rather
The multitudinous seas incarnadine,
Making the green one red:"—*Macbeth.*

IN the tough and stirring days in which he lived, Shakespeare can scarcely have failed to notice that a dilute solution of blood is yellow in hue instead of red, but at least he had no opportunity to learn that the same change of hue is also apparent when blood corpuscles are examined under a microscope. This observation, which has been the subject of recent correspondence in NATURE[1,2,3], appears at first sight to be one of those odd effects which can only be explained by reference to some peculiarity of vision. Actually it is an interesting and important example of the general phenomenon of dichroism, an all-embracing term used to describe the changes in hue which some media and surfaces undergo in certain conditions. Thus dichroism includes changes in hue which are observed with some media, such as blood, when their thickness or concentration is varied, the very striking and dramatic changes in colour of certain dyed materials when viewed successively in daylight and in artificial light, and the undertone of a pigment which is observed to differ in hue from that of the mass of the pigment when the latter is greatly extended with white. While it is true, as will be seen later, that certain visual factors are involved, yet the phenomenon has an essentially physical origin which is revealed when calculations are made to determine the spectral composition of the light reaching the eye.

The coloration of a medium is due to the freer transmission of some parts of the visible spectrum than others; thus a pigment which transmits mainly in the long-wave end of the spectrum will be red, one which transmits both the red and blue radiations will be purple, and so on. If, then, we wish to discover how the colour of a medium changes on reduction in thickness or on dilution, we have first to derive the spectral transmission curve for each thickness or concentration. As an example, consider a hypothetical medium in which the transmission factor T_0 for unit thickness and unit concentration of the medium is given for each wave-length in the visible spectrum by curve A in Fig. 1. In this case we have maximum transmission in the green at a wave-length of $0 \cdot 52\ \mu$ with a rapid and roughly symmetrical decrease on each side of the maximum, and we can conclude that the sample will possess a deep green colour. Further, we can use curve A to calculate the transmission curve for other thicknesses (or concentrations) by applying Beer's and Lambert's laws. These laws can for the present purpose be conveniently expressed by the equation

$$T = T_0^{cl},$$

where T is the transmission factor for wave-length λ for a concentration c and thickness l, while T_0, as stated above, is the transmission factor for the same wave-length but for unit concentration and unit thickness. (This relation is satisfactory, provided the reflexion losses at the surfaces of the medium are neglected.) Applying this equation for the cases when $c = 1$ and $l = \frac{1}{3}$, $\frac{1}{10}$ and $\frac{1}{30}$, we obtain three new transmission curves B, C and D respectively (Fig. 1).

Reduction in thickness is seen to increase the transmission at all wave-lengths, but it will also be noticed that the increase is relatively very much greater at those wave-lengths which are most absorbed. The extent to which the green wave-lengths are in excess of the other radiations thus steadily diminishes with reduction in thickness so that, with the thinnest specimen, curve D, the transmission curve shows only a slight decline on either side of $0 \cdot 52\ \mu$. It is then easy to understand why, when each specimen is illuminated in turn by a beam of white light, the deep green coloration becomes progressively paler or more desaturated until, in the case of curve D, it is reduced to a white with merely a tinge of green.

Since no obvious change of hue will accompany the desaturation, the effect would not appear in any way abnormal and would give no occasion for comment. This, however, is due to the hypothetical absorption curve assumed in Fig. 1, a curve which is more regular and more symmetrical than that found for most absorbing media. It is not difficult to see that if there had been a subsidiary maximum of transmission at some wave-length other than $0 \cdot 52\ \mu$, say in the red, then the relative transmissions of red to green would have changed with different thicknesses of the medium and the hue of the specimen would have moved from green towards the yellow as the red component in the transmitted light became increasingly effective. Or again, if there had been some heavy absorption at a particular part of the spectrum, then when a very thin layer was examined, all wave-lengths except those in or near the absorption band would be

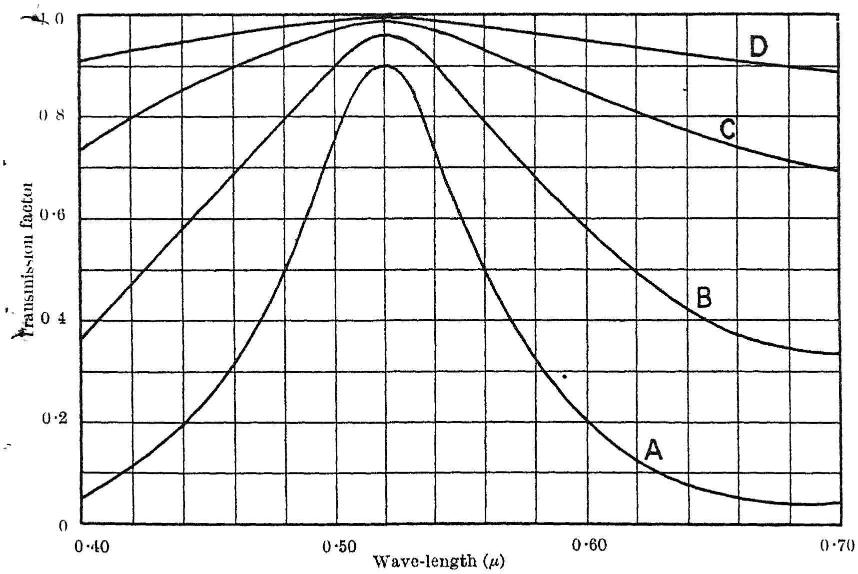

Fig. 1. SPECTRAL TRANSMISSION CURVES FOR DIFFERENT THICKNESSES OF A HYPOTHETICAL GREEN MEDIUM.

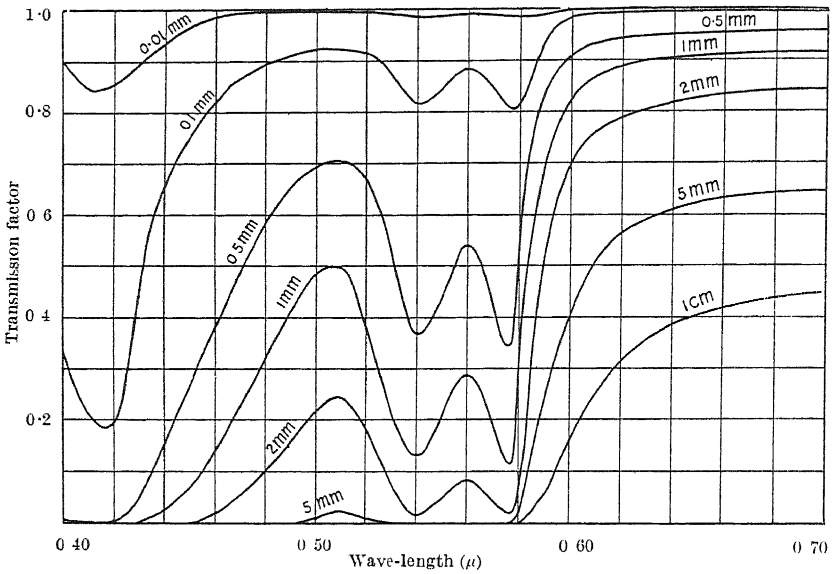

Fig. 2. SPECTRAL TRANSMISSION CURVES FOR DIFFERENT THICKNESSES OF OXYHÆMOGLOBIN (1 PER CENT CONCENTRATION). THE THICKNESSES OF EACH LAYER ARE SHOWN AGAINST THE CURVES.

transmitted with little loss in intensity, yet within the absorption band the reduction might still be appreciable. In that event, the specimen would acquire a hue complementary to that of the absorbed wave-lengths.

As it happens, the transmission curve of hæmoglobin shows that both characteristics—a strong absorption band and a subsidiary transmission maximum—are present to cause the change in hue from red to yellow which is observed with decreasing thickness and concentration. Thus, from the colorimetric point of view, the most important features of the transmission curve of blood are the high transmission at the long-wave end of the spectrum, the secondary peak in the transmission at a wave-length of 0·51 μ and the very strong absorption band in the violet at 0·42 μ.

The complete transmission curves of oxyhæmoglobin (1 per cent concentration) for thicknesses ranging from 1 cm. to 0·01 mm. have been calculated from data given by Heilmeyer[4] and are illustrated in Fig. 2. It is seen from this diagram that for the thickest layers, the only radiations transmitted in any strength are those at the red end of the spectrum, and it is this transmission which is responsible for the deep red colour normally observed. For layers of intermediate thickness the transmission around 0·51 μ in the green and blue-green becomes comparable to that in the red and will cause some change in the hue towards the orange or yellow, assisted also by the transmission at 0·56 μ. For very thin layers, on the other hand, there is practically complete transmission of all wave-lengths except in the violet, where some significant absorption still occurs. This will have the effect of tingeing the layer with the hue complementary to violet, namely, yellow, and will therefore introduce a change of hue of the same character as that caused by the transmission in the green. The similarity in the trend of the two effects is, however, a coincidence; if, for example, the strong absorption band had been located in the yellow while the absorption in the blue had been less severe, the hue at intermediate thicknesses would have first moved towards the yellow, yet in very thin layers it would have shown a slightly bluish tinge.

Although the spectral transmission curve of a medium gives a complete physical picture of the changes in light transmission which occur with change in thickness, the estimation of the colour as such can at best only be approximate, since no account is taken of the manner in which the different spectral radiations combine in the eye. A more complete analysis may be achieved by expressing the colour in terms of a trichromatic equation on the C.I.E. system[5], in which the quality of the light is defined by the proportions in which three reference stimuli have to be mixed additively to produce the same colour sensation as that produced by the light under investigation.

The methods involved in colorimetric calculations of this kind are now well established and are employed extensively in technical problems, although there are many persons interested in colour to whom they are still unfamiliar. The experimental foundation for the system depends on the fact that a colour can be matched by a suitable mixture of three radiations, and further, that the quantities involved in the match obey the ordinary rules of arithmetic; that is to say, if the brightness of the test colour were halved, the amounts of the three matching radiations would also have to be halved to maintain a match, and so on.

Assuming that we know the amounts of the three reference stimuli which would be required to match unit energy of each monochromatic radiation in the visible spectrum, we can, by a process of multiplication and summation, reduce any beam of light, as defined by its spectral energy curve, to the visual equivalent of three stimuli mixed in the correct proportions. This result can be expressed by a tristimulus equation which, on the C.I.E. system, takes the form of an equation of the type

$$C = x'.X + y'.Y + z'.Z.$$

In this equation X, Y and Z represent the reference stimuli which have an internationally specified significance, while x', y' and z' represent the amounts of the stimuli required to match the colour C. We are in many cases only interested in the relative amounts of X, Y and Z, and it is then convenient to reduce x', y' and z' proportionately to make their sum unity, so yielding the unit trichromatic equation

$$C = x.X + y.Y + z.Z,$$

in which $x + y + z = 1$. Further details of the system may be found elsewhere[6,7,8].

To apply the method to the case of hæmoglobin, we must first define the quality of the illumination which is to be used when viewing the different layers of blood. It will be convenient to assume the use of one of the standard illuminants for colorimetry, namely, the C.I.E. source S_B which, with a colour temperature of 4,800° K., has a quality somewhat

similar to daylight. From the energy distribution of the light radiated by this source and from the transmission curves of oxy-hæmoglobin given in Fig. 2, the spectral composition of the light transmitted through each layer can be calculated. From the colorimetric data given in the C.I.E. tables, the relative amounts of X, Y and Z required to match each layer can be calculated on the lines indicated above, and the results recorded on the chromaticity diagram.

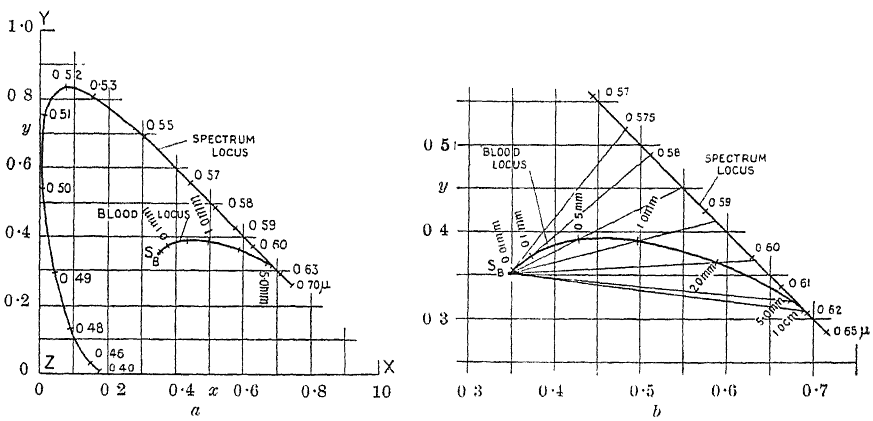

Fig. 3 (a) THE C.I.E CHROMATICITY CHART SHOWING THE SPECTRUM LOCUS, THE WHITE POINT S_B AND THE BLOOD LOCUS (b) AN ENLARGED SECTION OF THE CHART SHOWING THE BLOOD LOCUS AND PART OF THE SPECTRUM LOCUS. WAVE-LENGTHS ARE INDICATED AGAINST THE SPECTRUM LOCUS AND THE THICKNESS OF THE HÆMOGLOBIN LAYERS AGAINST THE BLOOD LOCUS.

This diagram is illustrated in Fig. 3, *a*. The values of x and y are recorded along the horizontal and vertical axes respectively, and the co-ordinates (x, y) of any point in the diagram provide a unique definition of a colour. (The third co-ordinate, z, is given by $z = 1 - x - y$.) The diagram is thus in the nature of a colour chart, but it also embodies the facts of colour mixture; for example, the result of mixing any two colours as defined by their positions on the chart is to produce a third colour located on the straight line joining the two colours being mixed. The locus of the spectrum colours in the chart is illustrated, as well as the position of the white point S_B. When a colour is represented by a point lying close to the spectrum locus, then it means that it is highly saturated with a hue similar to the monochromatic radiation to which it is a neighbour, but as it approaches S_B, so the hue becomes less pronounced and the colour becomes more desaturated.

We can now deduce the changes which take place in the colour of the blood layers. The points for each of the seven layers of Fig. 2 have been plotted in Fig. 3 to give the blood locus in the chromaticity diagram, a locus which starts near to the radiation $0 \cdot 62\ \mu$ and terminates, for extremely thin layers, at S_B. The locus is shown enlarged in Fig. 3, *b*. If straight lines are drawn from S_B through the points representing each layer and extended to intersect the spectrum locus, the points of intersection will give the dominant wave-length of each layer, that is, the wave-length of the monochromatic radiation which, when mixed in a suitable proportion with S_B, would match the colour of the layer. It is seen that the dominant wave-length ranges from $0 \cdot 62\ \mu$, an orange red, to $0 \cdot 575\ \mu$, a yellow, and we thus arrive at the numerical evidence for the change of hue which we deduced from general considerations from Fig. 2. If there had been no change in dominant wave-length with thickness, the blood locus would have been a straight line from the region of $0 \cdot 62\ \mu$ to S_B.

For a proper understanding of each case of dichroism, this type of colorimetric analysis is necessary. The case of hæmoglobin has been used as an example, but it could be applied equally well to those cases quoted, for example, by Paterson[9] or by Baker[1] and Webb[3], and to the changes occurring when coloured samples are viewed under different illuminations. Practically all absorbing media are to some extent dichroic in the sense that the colours of different layers do not lie exactly on a straight line when plotted in the chromaticity diagram, but in many cases the departure from linearity is too small to attract attention by any noticeable change in hue. On the other hand, there are many media, such as malachite green or quinoline blue, in which the change of hue is even greater than that of blood.

There remains one final consideration. The specification of a colour on the trichromatic system is a physical specification of the colour in the sense that it defines the mixture of three stimuli required to produce the same colour sensation as the test stimulus; no claim is made, or could be made, that it measures the sensation itself. While we can, from its position in the chromaticity diagram, state that a colour may be red or green or white, as the case may be, or, when comparing two colours, decide that one is yellower than the other, or more desaturated, and so on, we cannot give any precise description of the appearance of the colour under any given observing conditions, except to say that the three stimuli mixed in the correct proportions would have the same appearance under the same conditions. The appearance itself will be determined by a number of factors, such as the adaptation level and the conditions of contrast; thus when the intensity of a beam of light such as a spectral red or spectral green radiation is increased, the quality of the light appears to change in the direction of becoming whiter. These changes are due to adaptive processes in the retina and possibly in the brain, and they may lead to subtle effects which are by no means easy to evaluate.

Quite recently, however, Newhall, Nickerson and Judd[10] have studied these changes in connexion with an investigation of the spacing of the patterns in the "Munsell Book of Colour". They show, for example, that the 'constant-hue' locus in the chromaticity chart for patterns of decreasing saturation is not in general a straight line from the spectrum locus to the white point, but is a curved path, the shape of which varies from one region of the chart to another. This means that constancy of dominant wave-length does not necessarily imply exact constancy in the hue which an object appears to have. In the red corner of the chart it happens that the constant-hue locus has the same type of curvature as the blood locus, and thus tends to compensate to a small extent for the changes due to the physical dichroism of hæmoglobin, but for

other media the subjective dichroism, if that is an apt description of the phenomenon, may be equally liable to accentuate the change in hue.

U.S. NATIONAL PATENT PLANNING COMMISSION

By Sir WILLIAM JARRATT

DURING the past few years there has been considerable criticism of the patent system both in Great Britain and in the United States, and the impact of war has tended to intensify it in both countries. In America the criticism has been much more violent than in Great Britain, and many Bills dealing with alleged abuses in the patent system have been introduced in Congress, though none has become law. In view of this acute criticism, President Roosevelt, by Executive Order in December 1941, established a National Patent Planning Commission authorized, in conjunction with the Department of Commerce, to conduct a comprehensive survey and study of the American patent system, and consider whether the system provides the maximum service in stimulating the inventive genius of the American people in evolving inventions and in furthering their prompt utilization for the public good; whether the American patent system should perform a more active function in inventive development; whether there are obstructions in the existing system of patent laws and, if so, how they can be eliminated; to what extent the Government should go in stimulating inventive effort in normal times; and what methods or plans might be developed to promote inventions and discoveries which will increase commerce, provide employment, and fully utilize expanded defence industrial facilities during normal times.

The first report of the Commission, which has now been published (U.S. Superintendent of Documents, Washington, D.C.) is confined generally to the mechanics of patent law, and the use of patents. In an introductory statement, the Commission points out that the strongest industrial nations have the most effective patent systems, and it expresses the opinion that the American patent system is the best in the world. It recommends, however, that the system should be adjusted to meet existing conditions without destroying its basic principles, and it makes numerous specific recommendations for amendment of the patent law of the United States.

Two questions connected with the patent law but of general interest were also considered by the Commission, namely, "Patents and the War Effort" and the "Protection of the Public Interest". On the first question the report states that specific inquiries addressed particularly to representatives of the War and Naval Departments failed to develop any serious instances in which the patent system had interfered with the prosecution of the War. The Commission expresses the opinion that the outcome of the present War, more than any previous war, will depend upon a continuous superiority in science and invention, and that "never before has there been such a free exchange of scientific and technological knowledge and products of invention between our industrial concerns, our research laboratories, and our Government, and between our Government and our Allies. Such a liberal and complete exchange of scientific information and the secrets of industrial laboratories could not have been possible without the reassurance of the protection afforded by the patent system. The American people should recognize the part the system is thus playing in the free exchange of scientific information which is proving so effective in the prosecution of the war and which is so essential to ultimate victory." It is pointed out in the report that the existing law permits the American Government and its contractors to manufacture and use any patented or unpatented invention on payment of reasonable compensation, and the evidence taken by the Commission indicates that the law is adequate to protect the Government during the present national crisis. The British Government has, of course, similar powers conferred on it, and is given similar protection, by Section 29 of the Patents and Designs Acts, 1907 to 1942, which enacts the right of the Crown to use patented inventions and sets out the procedure for determination of the royalty or other compensation payable.

The Commission considered the question of the protection of the public interest from many points of view, the most important being whether it would be in the public interest to incorporate in the law a general compulsory licensing system, that is, a system under which every patentee can be compelled to allow his invention to be manufactured or used by another person on payment of a royalty or other compensation. It was felt that such a system would affect American needs adversely and would produce detrimental effects in foreign countries; and in consequence the conclusion is reached that it would not be advantageous to incorporate a compulsory licensing system in American patent law. The Commission was, however, impressed with the need of a degree of compulsion in certain fields, such as national defence, public health, and public safety, and it recommends in respect of these cases a system whereby in an action for infringement "the recovery of a patent owner shall be limited to reasonable compensation without prohibiting the use of the patented invention". It is interesting to note that this recommendation of the Commission would bring the American law into closer agreement with Section 38 A of the Patents and Designs Acts, 1907–42, of Great Britain, which enacts that, in the case of any patent for an invention for the preparation or production of food or medicine, the Comptroller of Patents shall, unless he sees good reason to the contrary, grant to any person a licence to use the invention, and in settling the royalty or other compensation payable, the Comptroller shall have regard to the desirability of making the food or medicine available to the public at the lowest possible price consistent with giving to the inventor due reward for the research leading to the invention.

On the general question of patents, the American people and their Government are urged by the Commission to recognize the fundamental rightness and fairness of protecting the creations of its inventors by the patent grant, and the Report states that the American patent system has: (1) encouraged and

rewarded inventiveness and creativeness, producing new products and processes which have placed the United States far ahead of other countries in the field of scientific and technological endeavour; (2) stimulated American inventors to originate a major portion of the important industrial and basic inventions of the past hundred and fifty years; (3) facilitated the rapid development and general application of new discoveries in the United States to an extent exceeding that of any other country; (4) contributed to the achievement of the highest standard of living that any nation has ever enjoyed; (5) stimulated creation and development of products and processes necessary to arm the nation and to wage successful war; (6) contributed to the improvement of the public health and the public safety; and (7) operated to protect the individual and small business concerns during the formative period of a new enterprise.

In view of a report so favourable to the present American patent system, it is of interest to note that the numerous important technical changes recommended by the Commission are almost uniformly of such a nature as to bring the American patent system more closely into accord with that of Great Britain.

TRICOTYLEDONY

By H. E. HOLTORP

TRICOTYLEDONY is well known as a sporadic occurrence in dicotyledonous plants, but it has apparently been treated in the past as a rare and somewhat trivial abnormality. I have been unable to trace any evidence of its being regarded as heritable.

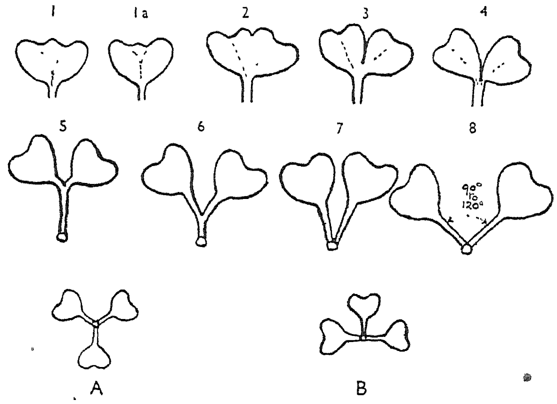
During the last few years I have collected tricotyledonous seedlings from a number of plants, the more important including various brassicas, wallflowers, *Dianthus sinensis*, carnations and carrots. These are mainly biennials, but I have also observed tricotyledony in certain annual dicotyledonous weeds and have more recently secured tricotyledonous tomatoes.

The observations, which I shall describe, have been made chiefly on brassicas (cabbage, savoy, cauliflower), for here the cotyledons are distinct in shape, substance and structure from the true leaves, even to casual inspection. This advantage is shared by tomatoes and carrots, but my investigations with these plants have not yet progressed so far.

I grew the first few tricotyledonous brassicas (generation P) to seed, isolated from other brassicas though not from one another. This seed yielded a considerable number of tricotyls in the S_1 generation. They were not counted, but there is no doubt that the proportion was higher than in the P generation. From this S_1 I selected seventeen of the most symmetrical tricotyls and again seeded them under similar conditions. The next generation (S_2) contained not only some hundreds of tricotyls, but also eighty tetracotyls—a form of which I had not seen a single example in thousands of brassica seedlings before this generation. Again I have selected and planted, in separate groups, the best tricotyls and tetracotyls for an S_3 generation in 1944.

It is thus clear that tricotyledony is a heritable character and one which can easily be changed by selection. Dicotyledony must then be adaptive and maintained by natural selection.

Pleiocotyls are not alike in form, and are not all to be traced to the same kind of variation in the seedling



structure. Seedlings must be grown to a considerable size before adequate description and classification are possible.

In brassicas I have recorded three main types of tricotyledony, each subject to its own characteristic variation, under the headings: (*a*) *simple fission*, (*b*) *twinning*, complete and incomplete, and (*c*) *supplementation*.

Fission. This appears as simple splitting of a cotyledon, from the notch in the terminal edge along the central vein towards the petiole. The split varies in length, the most extreme case seen being one of two elliptical pieces of tissue with separate stalks joined to form one petiole. Seedlings in this class are viable and grow into healthy plants, but the split cotyledon is always distorted and lags behind its normal fellow in growth.

Twinning. The diagram represents various forms of twin cotyledons and their petioles as found, together with all intermediate forms, in the brassicas. The simplest form (1) is a two-notched broad cotyledon in which the central peak is quite commonly not prominent (1*a*). The mid-vein is noticeably forked. This form is very common and is the only one which (except for true tetracotyls) occurs often in both cotyledons of a seedling. The remaining types are not infrequent though the symmetrical tricotyl (*A*) is somewhat rare, just as is a perfectly symmetrical dicotyl.

Supplementation. This variant has been quite common in the progeny of tricotyls after selection. Three main classes have been distinguished.

(1) The seedling is apparently normal and dicotyledonous, but the first subsequent true leaf, instead of being of the characteristic rough type, develops as a third cotyledon identifiable by substance, structure, venation and petiole, and even, in many cases, by its shape. It is, however, never a normal cotyledon, for its shape never changes by growth once it has developed. It grows but little after development, unlike the normal true leaf. This third cotyledon replacing the first true leaf may be (*a*) nearly but not quite a normal cotyledon, (*b*) clearly cotyledonous but incomplete, varying from the major portion of a cotyledon down to little more than the central vein, (*c*) clearly cotyledonous but with one lower quadrant, or perhaps a little more, showing a serrated edge like a true leaf, or (*d*) rarely, with about one half cotyledonous and the other more like a true leaf.

(2) The third cotyledon appears in rare cases in place of the second true leaf, after a first normal true leaf has been produced. It may even appear in place of the fourth leaf after three true leaves. Though

definitely cotyledonous, these were deformed and incomplete. In the case where the cotyledon replaced the fourth leaf, it consisted of a petiole about 3 in. long, bearing a relatively small lamina split down the centre with the two halves divergent.

(3) The third cotyledon is occasionally borne opposite the first true leaf at one node instead of being at a separate node.

Seedlings showing supplementation grow well into good plants. In general, however, fission and supplementation do lead to local malformation, though twinning does not.

Tricotyledonous brassica plants sometimes bear a pair of true leaves at the first node, or the first or second leaf may be incompletely twinned. Similarly in the wallflower, carnation and *Dianthus sinensis*, tricotyledony is often accompanied by the occurrence of three true leaves at the first, and sometimes also at the second, node.

Thus pleiocotyledony in brassicas occurs, as I find it, in several forms, counts of which should be made in the progeny of each type of tricotyledonous parent for the various forms can all be found among the offspring of one plant. I have estimated that the S_2 generation contained 25 per cent pleiocotyls of one kind or another, and a similar percentage has been found in a small test with the tomato. Pleiocotyly in an S_2 of wallflower, however, is as high as 40 per cent. Full analysis, however, involves growing all the seedlings to a size hitherto impossible in the conditions under which I have worked. I hope to obtain improved facilities in the future and so to obtain adequate counts in the selection lines.

I am indebted to Dr. K. Mather, of the John Innes Horticultural Institution, for advice on the interpretation of these observations.

SCIENTIFIC CENTENARIES IN 1944

By ENG.-CAPT. EDGAR C. SMITH, O.B.E., R.N.

AMONG the many men of science whose centenaries occur this year are representatives of England, Scotland, Ireland, France, Belgium, Sweden, Italy, Austria and America. Four hundred years ago, according to Silvanus Thompson, Gilbert was born; three hundred years ago, Castelli, Gascoygne and van Helmont died and Römer was born; two hundred years ago Celsius and Desaguliers died and Lamarck and Mechain were born, while among those who died a century ago were Dalton, Baily, Hope, Henderson and Geoffroy Saint-Hilaire.

On December 10, 1903, the exact tercentenary of the death of William Gilbert was commemorated by a meeting of the Institution of Electrical Engineers held at the Institution of Civil Engineers, at which the Royal Society, the Royal College of Physicians, St. John's College, Cambridge, the cities of Colchester and Westminster and the Société Internationale des Electriciens were represented. The address was given by Silvanus Thompson, who said "that electricians owed an enormous debt of gratitude to Gilbert, who, for them, was pre-eminent among all the great men of Elizabeth's time". The occasion was marked by the presentation to the City of Colchester of a picture representing Gilbert showing his experiments to Queen Elizabeth and her Court. The tomb of Gilbert in Holy Trinity Church, Colchester, gives the year of his birth as 1540, but Silvanus Thompson considered the correct date to be May 24, 1544.

Van Helmont (1577–1644), like Gilbert, was a physician, and for a short time filled a chair at Louvain; but his life was spent in philosophical studies and he was the first to recognize the existence of various aeriform substances to which he gave the name 'gases'. He was born in Brussels but died in Holland. Benedict Castelli (1577–1644) was an exact contemporary of van Helmont, and had the privilege of being taught by, and assisting, Galileo; he held chairs both at Pisa and Rome. William Gascoygne (1612 ?–1644), the inventor of the micrometer and a correspondent of Horrocks and Crabtree, died at about the age of thirty, fighting on the Royalist side at Marston Moor on July 2, 1644. Olaf Römer, the Danish astronomer, was born at Aarhuus, in Jutland, on September 25, 1644, and died at Copenhagen on September 19, 1710. His discovery of the velocity of light was made in Paris, when he was thirty-one; his famous transit instrument was made at Copenhagen, where he held the chair of astronomy. Many of his manuscripts were destroyed in the Copenhagen fire of 1728. The year 1744 saw the death of both Andreas Celsius and John Theophilus Desaguliers. Celsius was born at Uppsala on November 27, 1701. His travels took him to Germany, Italy and France, and then he went to Lapland with Maupertuis to measure an arc of the meridian. According to Cajori, Celsius marked his centigrade thermometer with boiling point as 0° and freezing point as 100°, and it was his colleague Märten Stromer who inverted the scale. Desaguliers was nearly twenty years senior to Celsius, having been born at Rochelle on March 12, 1683. He was brought to England by his father, a Calvinist pastor who left France on the Revocation of the Edict of Nantes. The child, it is said, was smuggled aboard the refugee ship in a barrel. France's loss was England's gain, for Desaguliers succeeded Keill as a lecturer on experimental philosophy at Oxford, and then in 1713 began his work in London "where," he wrote, "I have with great pleasure seen the Newtonian Philosophy so generally received among persons of all Ranks and professions, and even the Ladies by the help of experiments". At his death, Desaguliers was buried in the Savoy. Of the two Frenchmen, Lamarck and Mechain, the former was born in the village of Bazentin (Somme) and the latter at Laon (Aisne). Lamarck began life as a soldier, and then held a post in a Paris bank. In 1774 he became a keeper in the Jardin des Plantes, and there, for a quarter of a century, he lectured on invertebrate zoology. He died in 1829, blind and poor. Pierre F. A. Mechain was a geodesist as well as an astronomer and hydrographer, and it was while still employed on the extension of an arc of the meridian to Barcelona that he died on September 20, 1805.

Coming to those who died a hundred years ago, one of the most famous was Étienne Geoffroy Saint-Hilaire, who was born at Etampes on April 15, 1772, and who did great work both for the Jardin des Plantes and the Museum. In Scotland, few were better known than Thomas Henderson (1798–1844) and Thomas Charles Hope (1766–1844). Henderson, a native of Dundee, began life as a lawyer's clerk, but his studies led him to become acquainted with Wallace and Leslie, and through his papers he gained recognition as an astronomer. After a year or two at the Cape of Good Hope, on October 1, 1834, he became the first Astronomer Royal for Scotland. His contemporary, Hope, was always a chemist, and from 1799 until 1843 occupied the chair of chemistry in

the University of Edinburgh, previously held by Black. To him we owe the discovery of the maximum density of water. The centenary of John Dalton falls on July 27 of this year, but any commemoration must inevitably be clouded over by the results of the air raid of December 24, 1940, when the premises of the Manchester Literary and Philosophical Society were completely destroyed. From 1817 until 1844 Dalton was president of the Society, and within its walls he taught, lectured and experimented. The Society had an unequalled collection of his apparatus, but after digging among the ruins the only things found were his gold watch, a spark eudiometer and some charred remains of letters and note-books. A month after Dalton passed away in Manchester, Francis Baily died in London, after a life devoted to astronomy and kindred subjects. "Few men have left behind them so enviable a reputation. He was gentle as well as just; he loved and sought truth; he inspired in an equal degree respect and affection."

As is usual in these annual reviews of the centenaries of men of science, names of notable men born a century ago crowd closely upon one another, but it will perhaps be agreed that all those mentioned below have claims to recognition. Among the ranks of the physicists born in 1844 were Sir William F. Barrett (died 1925), who for more than thirty years held a chair in the Royal College of Science, Dublin; Sir William Abney (died 1921), who did much to put photography upon a scientific basis; and Ludwig Boltzmann (died 1906), professor of mathematical physics in the University of Vienna. Boltzmann died a tragic death, and his successor, F. Hasenöhrl, was killed in action on the Italian front in 1915. The chemists born in 1844 include Prof. J. Emerson Reynolds (died 1920), who occupied for twenty-eight years the chair of chemistry in the University of Dublin, and Ferdinand Hurter (died 1898), a native of Schaffhausen, Switzerland, who came to England in 1867 and became principal chemist to the United Alkali Company. Among astronomers, Prof. W. R. Brooks (died 1921) of the United States was famous as a 'comet hunter'. Charles Trépied (died 1907) was for many years director of the Observatory at Bouzariah, eleven kilometres from Algiers, while Annibale Ricco (died 1919), though he began life as an engineer, for nineteen years directed the observatory of Catania and Etna, his special subject being solar physics. In another sphere of scientific activity, Henry Alleyue Nicholson (died 1899) held professorships at St. Andrews and Aberdeen, and was Lyell medallist in 1888, while Auguste Michel-Lévy (died 1911) was director of the Geological Survey of France. A notice of the life and work of Michel-Lévy was read at a sitting of the Paris Academy of Sciences on December 21, 1914, under the shadow of war. The opening sentences ran, "Aux heures les plus graves de notre histoire nationale, l'Académie des Sciences a toujours tenu à proclamer bien haut sa foi inébranlable dans les destinées de la Patrie en n'interrompant en rien l'ordre régulier de ses travaux. C'est pourquoi, alors que notre territoire est encore envahi par l'ennemi, l'un de vos Secrétaires perpétuels vient, comme de coutume, vous rappeler en cette séance annuelle le souvenir de l'un de nos confrères disparus."

OBITUARIES

Sir Edward Poulton, F.R.S.

EDWARD BAGNALL POULTON, who died on November 20, was born on January 27, 1856. His school life was spent at Oakley House, Reading, until he was nearly seventeen, when he commenced work in the office of his father, who was an architect. His interest, however, was so obviously in science that he was allowed to work for a scholarship, attending Rolleston's lectures at Oxford. He obtained an open scholarship in science at Jesus College in 1873, and after a crowded three years took a first class in the honour school of natural science. Next year he was appointed demonstrator in zoology under Rolleston, whose virile personality greatly impressed him. But working as one of his staff under him was a very different thing from being one of his students, and Poulton could do little research. During the long vacation, however, he was inspired by Foster and Balfour's work on embryology to follow their methods, and as a result was given a class to teach in that subject. His income being inadequate, he studied for a University scholarship in geology under Prestwich, eventually obtaining the Burdett-Coutts Scholarship. Thus it came about that, having resigned his demonstratorship, his first research was conducted on a geological subject, and his first paper was published in 1880 on remains in quaternary sands at Reading.

Rolleston was succeeded by Moseley in 1881 and Poulton, by now lecturer at Keble and Jesus Colleges, found him as helpful as Rolleston had been difficult. Moseley suggested that he should investigate some *Challenger* material, and as a result of his studies three papers were published in 1883 on the tongues of several Australian animals, including Ornithorhynchus. An investigation of the structure of the hair of this primitive creature then followed, sections of the head of an immature specimen having been lent by Dr. W. K. Parker. This resulted in a discovery of fundamental importance, for Poulton announced in 1888 that Ornithorhynchus possesses true teeth which cut through the gums but are replaced by horny plates.

But although he was professionally occupied with morphology, Poulton's real interest was in living insects. Such entomological studies as he saw being conducted by Westwood at Oxford did not, however, appeal to him, for they were concerned mainly with systematics. Poulton had read Wallace's essays on natural selection in 1878, and these aroused what he described as "a lifelong delight" in the subject of the coloration of animals, particularly of insects. Weismann's studies in the theory of descent, of which he read in 1883 a translation by his friend R. Meldola, contained an account of variation in the colour of a caterpillar according to its surroundings, which especially interested Poulton, as it recalled observations he had made in boyhood upon that very species.

He began to work at once on that subject, and, amidst his morphological work, produced during 1884–88 a succession of papers on the colours of larvæ and pupæ and on experiments to test the factors influencing them, and their survival value. These researches led to his election to the Royal Society in 1889, and in 1890 his great work "The Colours of Animals" at once set him in the front

rank of upholders of natural selection, and until recently held the field as a comprehensive guide to the meaning of all forms of coloration. He became known as an ardent champion of pure Darwinism, finding in it a satisfying explanation of countless phenomena of colour and habits which, he always emphasized, must be studied and explained together. He first read "The Origin of Species" in 1875 as an undergraduate, and throughout his life it was almost like a Bible to him. He explained, in two books, the principles on which it was based, to aid those who, perhaps, felt the masterpiece rather too much for them.

The extravagant claims of the early mutationists particularly distressed Poulton, and he fought against the idea which Sir Oliver Lodge neatly expressed at the British Association in 1913—that not only is it untrue to say '*Natura non fecit saltum*' but that it is doubtful if she ever does anything else. Partly, perhaps, for this reason and partly because mathematics were as incomprehensible to him as to the master he served, he was never attracted by genetics, though heredity greatly interested him, and he took much interest in eugenics.

The death of Westwood left vacant the recently founded chair of Hope professor of zoology at Oxford, and Poulton was elected to it in 1893: there could scarcely have been a greater change. Westwood had been mainly occupied in the prevalent mode of adding to knowledge by describing new species and classifying them. In this he won world renown, but he did not move with the times, and warned Poulton against the dangers of the new doctrine. It was an irony that the young man so warned became one of its most forceful exponents. One of the first applications of Darwinism to problems of field natural history was the theory of mimicry, propounded by Bates in 1862, which explained the deceptive, superficial resemblance of one species of butterfly to another better protected by unpleasant qualities against the attacks of predators. Mimicry became one of Poulton's chief subjects, and all that he and his friends did to make known the extent of the phenomena convinced him that no explanation covers all the facts so well as natural selection. Critics have not always troubled to understand thoroughly the problems involved in mimicry, and it is a pity that the logical terms which Sidgwick devised for Poulton ("pseudaposematic" and "synaposematic") are not more generally used. If these types of coloration are due to selective preferences of predators, then upholders of the theory must produce evidence, and Poulton continually urged naturalists to observe and experiment in the field. A large body of facts has thus been accumulated, but it is not unfair to say that Poulton was not statistically minded; and most of the records, while adding more and more instances of observed cases, are not satisfying to the inquirer into "*How much* better ?" or "*How much* more often ?"

It was one of Poulton's correspondents who first showed that, when a bird attacks a butterfly and releases it, the shape of the bill is recognizably imprinted upon the wing, and much work on this subject has been done which goes to show that birds are probably the selective agents which theory requires for the production of mimicry in butterflies. On the other hand, if vertebrates avoid certain species as relatively distasteful, it is possible that these are destroyed by insect predators, and this point was also urged by Poulton, and evidence shows that this is so.

The importance of the fact that 'edibility' is relative, and merely a function of abundance, is frequently overlooked by critics. This point was emphasized by Poulton. The value of mimicry closely depends upon geographical distribution, and studies made by Poulton and his associates have shown that in such remarkable polymorphic species as *Papilio dardanus* and *Pseudacraea eurytus*, the prevailing form of the mimetic species corresponds numerically with the species of model most abundant in the locality. Moreover, if the protective influence of a model is removed by its decline in numbers, or by the mimetic species occurring in localities from which models are absent, the mimic is uncontrolled by selection and the mimetic resemblance deteriorates.

A Darwinian may be expected to show interest in sexual selection, and Poulton's influence resulted in important discoveries of structures used to produce scent in courtship, and of habits displaying special colours before the female. The extraordinary behaviour of certain male flies (Empididae), closely studied by one of his assistants, was shown to constitute a complete evolutionary series in the development of an elaborate courtship.

All this involved immense labour in correspondence, but there was also the care of the great collections which grew embarrassingly, so that it became beyond his power to attend to every detail himself, and he was very insistent upon detail; thus to anyone but Poulton himself there seemed to be considerable confusion. He paid particular attention to making a label tell the whole story of a specimen, so that Hope Department labels are recognized to be the most informative in any collection in the world. But his passion for making the title of a communication summarize all the contents often proves a trial to bibliographers.

After his retirement in 1933, Poulton's friends hoped that, freed from the care of the department which he had made renowned, Poulton would settle down to the production of his *magnum opus*, but this was not to be. He was unable to shake himself free from the toils of correspondence; his powers weakened, his memory began to fail, and kindly death took him peacefully while he was still happy and interested.

His distinctions were many. He served on the Council of the Royal Society during 1897–99 and 1908–10; was vice-president during 1909–10 and Darwin medallist in 1914. He presided over the Linnean Society during 1912–16 and was Linnean medallist in 1922. When the second International Entomological Congress met at Oxford in 1912, he was its president; in 1915 he gave the Romanes Lecture. He thrice presided over the Entomological Society, the last occasion being at the centenary meeting in 1933, at which it became a Royal Society. Several universities, at home or abroad, conferred honorary doctorates upon him, and he was an honorary member or correspondent of many learned societies.

Friendly, affectionate and uncompromisingly truthful, he was a great believer in intercourse and a habitual attendant at the British Association meetings, at which he presided in 1937 and with which he went to South Africa and Australia. He also visited North America, and everywhere established links of closest friendship. He married in 1881 Emily, daughter of George Palmer, formerly M.P. for Reading, who predeceased him. They had two sons and three daughters, of whom only Mrs. Maxwell Garnett

survives him. There are thirteen grandchildren and three great-grandchildren to carry on his memory.

By the death of Sir Edward Poulton, natural history, as Darwin taught it, has lost a master. He will long be remembered for his life's work at Oxford; from it has flowed inspiration and help to naturalists seeking truth all over the world. They found him a never-failing counsellor and a generous friend whom they learnt to love. G. D. HALE CARPENTER.

Mr. H. F. Witherby, M.B.E.

THE death of H. F. Witherby on December 11 leaves a gap in the students of British ornithology which will be difficult to replace. He was the second surviving son of Henry Forbes Witherby of Burley, Hants, and was born on October 7, 1873. After leaving school he entered the old family publishing firm of Witherby and Co., and some years ago retired, but resumed work again after the outbreak of war.

Although a successful business man, the study of birds was Witherby's main interest in life, and for this purpose he made many trips abroad in search of birds. He was specially interested in Spanish ornithology, and contributed several papers on this subject to the *Ibis*. Early in his career Witherby became interested in migration, and with the object of studying this phenomena visited many well-known localities on the east coast, and in 1938 even venturing to Fair Isle.

In 1909 he started the 'British Birds' ringing scheme, which from a small beginning has grown to be of national importance and is now carried on from the British Museum under the auspices of the British Trust for Ornithology. In 1907 he founded *British Birds* magazine, and this soon brought him in touch with all those interested in the study of birds in these islands. With the help of others he published a "Handlist of British Birds" in 1912, and in 1912–24, with the assistance of other ornithologists, a "Practical Handbook of British Birds". When these volumes became out of print he published during 1938–41 a more ambitious work, the "Handbook of British Birds", in five volumes; this has rightly been described as the best book on the birds of any country. Witherby himself was responsible for the systematic work and general editorship.

He had a very fine collection of both British and European birds which he sold to the British Museum, giving the proceeds to the British Trust for Ornithology, a body he took great interest in from the beginning. His collection was very carefully made, mainly for the purpose of studying races and plumages. Together with the late Dr. C. B. Ticehurst he did much to elucidate the moults and sequence of plumage of our native birds—indeed it might be said of European species also. It was Witherby who cleared up the long-disputed question as to how the rook developed its bare face, and in an article in *British Birds* proved it was a matter of age, not wear. Witherby was a very careful and painstaking worker, and would take an enormous amount of trouble before admitting a new species to the British list, or a record of a rare visitor. The late Dr. Hartert may be said to have introduced the trinomial system into ornithology in Great Britain, and Witherby was one of the first to appreciate the importance of this step.

As editor of *British Birds*, Witherby occupied a unique position in the study of our native birds, and he will be sadly missed by his many friends and correspondents; to beginners he was especially helpful and encouraging. During 1924–27 he was chairman of the British Ornithologists' Club, and president of the British Ornithologists' Union during 1933–38. On his retirement he was awarded the Godman-Salvin Medal for his work on ornithology.

In 1904 he married Lilian, daughter of the Rev. S. Gillson, and leaves two sons and three daughters.

N. B. KINNEAR.

NEWS and VIEWS

Secondary Education in Great Britain

THE valuable statement "The Open Door in Secondary Education", issued by the members of the Education Sub-Committee of Nuffield College Social Reconstruction Survey, does full justice to the twin aims of educational reform: maintenance of the quality of the education provided, while making sure that opportunities at present the privilege of a minority become the heritage of the nation. Its six recommendations are accompanied by a brief survey which indicates the rapidity with which opinion has advanced in this field. First, the Statement recommends that in all schools which receive any grants from the State or from local education authorities, tuition should be free and adequate maintenance grants should be given. Secondly, the scales on which grants are made to schools should vary according to the education they provide, especially in equipment, staffing ratio and opportunities for advanced work. To deal with the allocation of grants and with the question of control involved in this second recommendation, establishment by the Board of Education of a school grants central committee on the lines of the University Grants Committee is proposed, assisted by a small number of regional committees.

All schools for children between the ages of eleven and eighteen should be inspected by the Board of Education at intervals of not more than five years. All private schools which have not yet been formally recognized should be required to obtain from the Board a certificate of efficiency: but no school should be closed by the Board of Education without the right of appeal to an independent tribunal. One member of the Committee, Sir Richard Livingstone, regards this proposal as too drastic and open to abuse, and would tackle the evil of the undesirable school by giving a certificate to schools which submit to voluntary inspection and are approved, or by refusing anyone leave to teach who does not hold a university degree or has not attended an approved course for training in teaching.

The Statement then recommends that the school grants committee and the local education authorities should be empowered to make grants to children to enable them to pass from schools under their jurisdiction to independent private schools if they secure places in them. Maximum grants should be fixed by the school grants committee. Finally, such grants should only be made to children entering schools which observe the following conditions to the satisfaction of the Board of Education: (*a*) that to the extent of their normal numbers they admit children

according to their capacity to profit by the education provided, and not according to their parents' needs; (*b*) that the schools provide from their own resources any sums needed above the maximum grants specified to pay the fees for any pupil they admit who may need further assistance; and (*c*) that the schools devise or accept tests of suitability for entry with enough options to enable children who have had different types of early education to show ability to profit by the education given in the schools.

Scientific Men in Government Service

ALTHOUGH the article "Science and Government" by Dr. H. G. Moulton, president of the Brookings Institution (published in *Science* of December 11, 1942, which has just been received), is mainly concerned with relations between scientific workers and the Government of the United States, it is of some interest with regard to current discussions in Great Britain on the place of science in government. Dr. Moulton covers a wide field, including scientific research into the machinery of government as well as the conduct of scientific research by government and the use of scientifically trained men by government, and he suggests that the surest means of resolving the prevailing confusion of our time and of finding solutions to the baffling problems now confronting civilization lies in a re-integration of knowledge through the systematic study of the various fields of science conceived as a whole. This is the primary function of the university, but the failure of the U.S. Government to make more effective use of science in the determination of policy is attributed to shortcomings in the organization of the American system of government and politics. Dr. Moulton points out that while the scientific men in government departments may assemble the data required with true scientific objectivity, they are usually debarred from interpreting the data or formulating conclusions to be drawn therefrom. There is no easy road to efficiency in government. Scientific men, business men and the general public must take an active and continuous interest in government, keeping themselves informed on the issues involved and electing honest, public-spirited and able servants. Public office-holding must be made a high calling, a worthy and rewarding career for anyone, and representatives must be encouraged to think in terms of the national welfare as a whole, rather than in terms of sectional or local interests.

Sugar Research Foundation

DR. ROBERT C. HOCKETT, associate professor of organic chemistry at the Massachusetts Institute of Technology, has been appointed scientific director of the Sugar Research Foundation. Following his graduation from Ohio State University, Dr. Hockett served there as graduate assistant in analytical chemistry. As a fellow of the National Research Council, he went to the National Institute of Health, United States Public Health Service, where he worked with Dr. C. S. Hudson. Dr. Hockett later became associate technologist of the Institute of Health and served in that position for several years. Since 1935, Dr. Hockett has been at the Massachusetts Institute of Technology, where he has developed a research programme on the chemistry of carbohydrates. Mr. Joseph F. Abbott, president of the Sugar Research Foundation, said that this appointment is the first step in a new scientific programme to extend knowledge of the role of sugar and other carbohydrates in the human body and also of the chemical transformations to which sugars can be subjected. It is anticipated that such chemical studies, both fundamental and applied, will eventually indicate new industrial uses of sugar and its derivatives. Dr. Hockett has been granted five years leave of absence from the Massachusetts Institute of Technology to carry on his new work with the Foundation.

Mr. Abbott pointed out that the aims of the Sugar Research Foundation, which is a non-profit organization with offices at 99 Wall Street, New York 5, N.Y., and was formed last June, include the promotion of research and scientific studies at universities and other research institutions on the uses of sugar, and the dissemination of accurate information concerning sugar. It is supported by cane sugar refiners and beet sugar processors, as well as raw sugar producers of Hawaii, Louisiana and Puerto Rico. It is believed that research on the proper balance between carbohydrates and other food elements in the diet will do much to aid the public in utilizing intelligently low-cost energy foods, such as sugar. This will be of obvious importance during the present period of world-wide food shortages, and for some time after the cessation of hostilities, when populations will have to be fed on diets containing a high proportion of sugars and other carbohydrates.

Development Advisor for West Africa

THE Secretary of State for the Colonies has appointed Mr. N. F. Hall, director of the National Institute for Economic and Social Research, to be development advisor for West Africa. He will be on the staff of the Resident Minister and will act in close consultation with the Governments of Nigeria, the Gold Coast, Sierra Leone and the Gambia, which have been working for some time on plans for post-war development. Mr. Hall has been on leave of absence from the National Institute since 1938 for war duties, and has served as joint-director of the Ministry of Economic Warfare; and more recently has been in charge of economic warfare work at the British Embassy, Washington, where he held the rank of Minister in the Diplomatic Service.

Mr. Maxwell Fry has been appointed town-planning advisor to the West African Governments; he will assist in the preparation of schemes for the large-scale housing and town-planning which is contemplated by these Governments.

Welsh Secretary of the Ministry of Agriculture

MR. J. MORGAN JONES, registrar of the University College of Wales, Aberystwyth, has been appointed Welsh Secretary of the Ministry of Agriculture in succession to Dr. C. Bryner Jones as from March 31, 1944. Mr. Morgan Jones is the son of a Montgomeryshire farmer, and a former student of the University College of Wales, Aberystwyth. In 1924 he joined the staff of the newly established Advisory Department in Agricultural Economics of the College and remained as a member of Prof. A. W. Ashby's staff until 1930. In that year he was appointed to the Markets Division of the Ministry of Agriculture. He returned to Aberystwyth at the end of 1935 to become registrar at his old College. During the War he has been closely connected with the food production campaign in Wales in the capacity of Minister's liaison officer for the counties of Cardigan, Pembroke, Carmarthen, Brecon and Radnor, and more recently

also as chairman of the Cardiganshire War Agricultural Executive Committee. Dr. Bryner Jones will continue to act as one of the Minister's liaison officers for Wales.

Veterinary Surgeons and Military Service

A JOINT statement was issued by the Ministry of Labour and National Service and the Ministry of Agriculture and Fisheries on October 5 announcing the setting up of the Army Service Veterinary Selection Committee to advise the Ministers concerned on the recruitment of veterinary surgeons for military service in their professional capacity. In order to provide full representation of the interests of veterinary surgeons in private practice, an additional member representing the National Veterinary Medical Association has been appointed to the Committee. This Committee has considered the cases of veterinary surgeons who have graduated since January 1, 1940, and who at present comprise the 'pool' from which the men needed for service in the R.A.V.C. will be recruited as required. Notifications of the Committee's decisions in these cases are being sent to the assistants concerned and also to their employers. It is expected that the number of veterinary surgeons thus made available to the R.A.V.C. will go some way, at least, to meet immediate needs. It is essential, however, in order to meet urgent military contingencies, to have a reserve of veterinary surgeons who may be drawn upon when necessary. It has accordingly been decided that the 'pool' shall be extended to include all veterinary surgeons born on or after January 1, 1914. The cases of these men will be dealt with on their merits, in accordance with the arrangements set out in the earlier announcement.

Economic Flux Density in Large Transformers

IN a paper read before the Institution of Electrical Engineers in London, D. J. Bolton pointed out that technical developments may at any time make it possible to increase the working densities in electrical machines and so enable a larger output to be obtained from a given frame-size and weight of active materials. The present paper assumes that an increase of transformer flux density is technically feasible, and tries to discover whether it is economically desirable. Only a single situation is examined, and only two, fairly large, sizes of transformer, such as would be used in the lower-voltage sections of the British Grid, are considered. The results are emphatically against any such increase, and in favour of densities lower than those in use at present.

Edible and Poisonous Plants of the Pacific Islands

A SMALL technical manual, prepared by Dr. E. D. Merrill of Harvard University, has been issued by the War Department of the United States, giving descriptions of the "Emergency Food Plants and Poisonous Plants of the Islands of the Pacific" (T.M. 10–420. Superintendent of Documents, U.S. Government Printing Office, Washington, D.C.). Although the manual is intended "to aid the individual who becomes separated from his unit" to sustain himself, it has a wider field of interest. More than a hundred of the more common edible tropical plants are figured, and each is accompanied by a short description with notes as to what parts may be eaten and how they should be prepared, together with a list of the plant names in local tongues. Nearly a dozen of the more virulent poisonous plants are also included. The simple, clear habit drawings are admirable. Occasionally human figures are included to indicate the scale, a practice which, perhaps, might have been followed more often. However, the whole makes an excellent handbook.

The Night Sky in January

FULL moon occurs on Jan. 10d. 10h. 09m. U.T., and new moon on Jan. 25d. 15h. 24m. The following conjunctions with the moon take place: Jan. 6d. 18h., Mars 8° N.; Jan. 8d. 04h., Saturn 2° N.; Jan. 13d. 11h., Jupiter 0·7° S.; Jan. 22d. 21h., Venus 2° S.; Jan. 22d. 23h., Mercury 0·1° S. The following occultations of stars brighter than magnitude 6 take place: Jan. 4d. 16h. 14.6 m. ξ^2 Ceti (*D*); Jan. 8d. 19h. 31·8m., 64 Orio (*D*); Jan. 9d. 00h. 52·5m., 68 Orio (*D*); Jan. 15d. 04h. 15·1m., 308B Leon (*R*); Jan. 16d. 05m. 03·9s., *b* Virg (*R*). The times refer to Greenwich and *D* and *R* refer to disappearance and reappearance respectively. Mercury is in inferior conjunction on Jan. 8. In the middle of the month it rises and sets an hour before the sun, the times at the end of the month being 6h. 27m. and 14h. 29m. Venus, a morning star, rises at 4h. 37m., 5h. 12m., and 5h. 44m. at the beginning, middle and end of the month respectively. Mars, in the constellation of Taurus, is stationary on Jan. 10. The planet can be seen through a great part of the night, being due south at 21h. 30m., 20h. 34m., and 19h. 42m. at the beginning, middle and end of the month, the times of setting on the corresponding dates being 5h. 45m., 4h. 50m., and 4h. Jupiter, in the constellation of Leo, rises at 20h. 07m., 19h. 04m. and 17h. 50m. at the beginning, middle and end of the month and is visible throughout the night. Saturn, in the constellation of Taurus, sets about an hour later than Mars at the beginning and middle of the month, and on Jan. 31 it sets at 4h. 39m. The earth reaches perihelion on Jan. 4, its distance from the sun being then 91,447,000 miles. There will be a total eclipse of the sun on Jan. 25, partly visible as a partial eclipse at Greenwich. The eclipse begins at Greenwich on Jan. 25d. 16h. 29m., but the magnitude of the eclipse will be only about 1/50, and this will occur about sunset. The Quadrantid meteors are due on Jan. 3 and 4; the radiant of this shower is at R.A. 15h. 20m., Dec. + 50°.

Announcements

THE Council of the British Cotton Industry Research Association announces that Dr. F. C. Toy has been appointed to succeed Sir Robert Pickard, who is relinquishing the post of director of research which he has filled for the last seventeen years. Dr. Toy has held the position of deputy director of the Association since he joined the Shirley Institute staff thirteen years ago. Dr. D. W. Hill has been appointed to succeed Dr. Toy as deputy director. Sir Robert Pickard has accepted the post of consultant to the Association.

ERRATUM. In connexion with the paragraph on the Duddell Medal award to Mr. J. Guild in NATURE of December 11, p. 686, reference was made to Mr. Guild's work on the improved goniometric spectrometer in collaboration with "the late Mr. George Watts". We are informed that Mr. Watts is still chairman of Messrs. E. R. Watts and Son, Ltd., and takes an active part in the daily work of the firm's factory.

Structure of Nucleic Acid in the Dividing Cell

RECENTLY Donovan and Woodhouse[1] advanced a speculation on the nature of the chemical structure which is the essence of the malignant cell. Their idea is the formulation of a molecule in the chromosome capable of splitting into two similar symmetrical portions, and this is envisaged specifically as a nucleic acid linked through pyrophosphoric acid to nucleotide groups. It is a moot point whether or not they are justified in regarding nucleic acid as the 'master constituent' to the exclusion of other known nuclear components. In this communication, however, it is desired to emphasize certain points concerning the chemistry of nucleic acids which arise from their communication.

Donovan and Woodhouse suggest that "when engaged in ordinary cellular activities, the cell has, as its essential basis, molecules of nucleic acid joined by pyrophosphoric linkings to nucleotides similar to" co-dehydrogenase I, thiamine pyrophosphate, riboflavine-adenine dinucleotide and phosphagen "which subserve its normal metabolic activity. When cell division is about to take place the metabolic nucleotides on one side of the linkage are replaced by, or are converted into, nucleotides which are the mirror image of those on the primary nucleic acid portion. The symmetrical, double nucleic acid then splits, with resultant division of the chromosomes accompanied by the associated phenomena which comprise 'cell division'. In the case of the malignant cell, however, [they postulate that] the symmetrical development of the dual nucleic-acid molecule proceeds directly and continually instead of via the usual attachment of the metabolic type of nucleotide groups."

The use of the phrase 'mirror image' is unfortunate, since it implies that the new molecule of nucleic acid will be the enantiomorph of the original. This would involve the existence of a molecule of nucleic acid differing profoundly from the original in its stereochemical structure, and as a consequence the two daughter chromosomes would be different, not identical, as is in fact the case in cell mitosis. Further, no nucleic acids containing enantiomorphic sugars have so far been recorded.

The structural diagram given by Donovan and Woodhouse for their proposed double nucleic acid is entirely without experimental basis since, so far as is known, no nucleic acid contains both pentose and desoxypentose sugars in the same molecule. It would, however, have been reasonable to assume that the nucleic acid entering into the cellular reactions postulated would be desoxyribonucleic acid, in view of the claims by Caspersson and others that it is comprised in the chromosomes.

Although it is true that the pyrophosphate group is common to several naturally occurring nucleotides, there is no evidence of its presence in isolated ribo- or desoxyribo-nucleic acids. That does not, of course, exclude the possibility of its occurrence in the living nucleus, but it should be realized that, in the formulation of the double nucleic acid by Donovan and Woodhouse, there are no dissociating groups in the phosphoryl radicles; such groups are generally regarded as participating in the union with the basic protein to form the nucleoprotein.

It is felt that, although simple chemical interpretations of the dividing chromosome and the malignant cell are much to be desired, it is unwise at present to attempt to limit consideration to one cell constituent alone. Furthermore, interpretations must be based on well-established facts, both biological and chemical, and simplification of the problem must not assume such importance that those facts are subordinated to it.

Aerial Disinfection

THE bactericidal action of propylene glycol vapour against air-borne bacteria has been recently discussed by Robertson[1]. The considerations he puts forward seem capable of general extension.

In order to kill bacteria suspended in the air, a lethal amount of the bactericidal agent must accumulate on the bacteria-carrying particles. The purely physical processes involved in this are at least as important as the bactericidal power of the substance itself. Condensation of the bactericide on to the bacterium will be favoured by: (*a*) saturation or near-saturation of the air with the bactericide; (*b*) solution of the bactericide in the bacteria-carrying particles, which may usually in this context be regarded as a watery solution. When equilibrium between the particle and the bactericidal atmosphere is established, the partial vapour pressures of bactericide and water in the atmosphere and over the particle will be equal. This equilibrium will be attained very rapidly with particles of a few microns in diameter. Death of the bacteria will follow if the concentration of bactericide in the final solution is lethal.

Working on this basis, desiderata for an aerial antiseptic would seem to be, in addition to bactericidal activity and lack of toxicity to man: (*a*) low vapour pressure, so that it is possible to work near to saturation; (*b*) water solubility, so that the bactericide will condense readily on to moist particles; (*c*) stability in room atmospheres, that is, freedom from liability to oxidation or other chemical decomposition, or to absorption by walls and textiles.

In addition to the phenols and the glycols, other classes of compounds appear likely to contain members fulfilling these conditions, for example the hydroxy acids or the amino alcohols. Tests have been made on the bactericidal activity of vapours of lactic acid, mandelic acid and triethanolamine. All these have given good kills of the organisms of sprayed saliva (*S. salivarius* and others) at concentrations of 10, 8 and 150 mgm./cu. metre respectively with relative humidities about 70 per cent and temperatures of 60–70° F.

More detailed experiments have been carried out with lactic acid, and good kills (better than 90 per cent in 5 minutes) have been obtained on the organisms of sprayed saliva at relative humidities ranging

from 40 to 85 per cent and on dust from a hospital blanket, mainly carrying a sarcina, at humidities of 60–80 per cent. Both heat volatilization of the pure acid, or its aqueous solution, and dispersal as a fine spray in aqueous solution, produce bactericidal atmospheres when the acid is in a concentration of 30 mgm./cu. metre; at one third of this concentration it is much less effective. The majority of the tests were carried out in an 800 cu. ft. room at 60–70° F. and the bacteria sampled on to serum agar plates in a slit-sampler[2]. The kill was confirmed by collecting the bacteria directly into broth in an impinger and plating out.

A Thermolabile Accessory Growth-factor to Rhizobium

IN addition to the thermostable accessory growth-factor (Allison and Hoover's coenzyme *R*), we have found a thermolabile accessory growth-factor to the root-nodule bacteria.

The medium was prepared by grinding 20 gm. of air-dried vetch powder (stem and leaves of *Vicia sinkiangensis*) with 20 c.c. normal caustic potash solution; when well rubbed, the paste was put into a cylinder containing 1,000 c.c. distilled water and was kept overnight. Next morning the supernatant fluid was transferred to a clean container, to which was added enough phosphoric acid to neutralize the alkali, and also 10 gm. sucrose and 3 gm. calcium carbonate. The resultant medium was then made up to 1,000 c.c., sterilized either by autoclaving for 25–30 minutes at 15 lb. per sq. in. pressure or by filtering through a Chamberland *F* (*L5*) candle attached to a filtering press. The autoclaved medium was distributed in 9-c.c. portions to test tubes before sterilization. The filter-sterilized medium was transferred to sterile test tubes aseptically after filtration.

Nodule bacteria strains 107 (of pea group) and 520 (of cowpea group) were used as test organisms. The inoculum was made up by washing a slant culture of the organism with approximately 10 c.c. of sterile water. A loopful of bacterial suspension was inoculated to each tube. The cultures were incubated at 25–30° C. for five days or more. Table 1 shows a typical result, in which cold sterilized medium gives more than three times the growth on autoclaved medium. Repeated experiments of the same kind established the presence of a thermolabile accessory growth-factor, stimulant, though not necessary, to the growth of root-nodule bacteria.

TABLE 1. DIRECT MICROSCOPICAL COUNT OF 11 DAYS BACTERIAL GROWTH (STRAIN 520) IN MILLIONS PER C.C.

Autoclaved medium	Cold-sterilized medium
31·5	114·0

A second series of experiments was then carried out to investigate the response of the thermolabile factor to heating. Test tubes containing cold sterilized vetch extract medium were heated for 30 min. at 40°, 60°, 80° and 100° C. in a water bath. In addition, unheated tubes and autoclaved tubes containing the same medium and autoclaved tubes containing the standard yeast-water-sucrose medium were included for comparison. Table 2 gives results of one experiment of this kind. The result shows that bacterial growth diminishes with increasing heating of the medium prior to inoculation, while there is no definite thermo-inactive point. The cowpea bacteria strain 520 seemed to have responded more readily to the thermolabile factor than that of the pea bacteria strain 107.

TABLE 2. DIRECT MICROSCOPICAL COUNT OF 5 DAYS BACTERIAL GROWTH IN MILLIONS PER C.C.

Strain	Yeast-water-sucrose	Auto-claved	Vetch extract medium				Not heated
			100° C.	80° C.	60° C.	40° C.	
520	139·1	0·6	44·8	43·6	59·2	71·5	128·0
107	143·6	78·6	85·2	119·0	105·3	120·2	126·1

Owing to the very poor laboratory equipment at our temporary war-time quarters, which are without a refrigerator to keep stock medium, and with crude chemicals, we were not able to give reproducible quantitative data between two independent sets of experiments. Nevertheless, within each individual experiment, the presence of a thermolabile factor which affected the growth-rate of root-nodule bacteria was unmistakable.

Further studies on this newly found factor are under progress so far as facilities and time permit.

Localization of Vitamin C in *Belascaris marginata*

THE distribution of vitamin C in many vertebrate tissues is now well known, but excepting the Protozoa, knowledge of its localization in invertebrate tissues is somewhat limited, and no work, to our knowledge, has been carried out on the Nematoda.

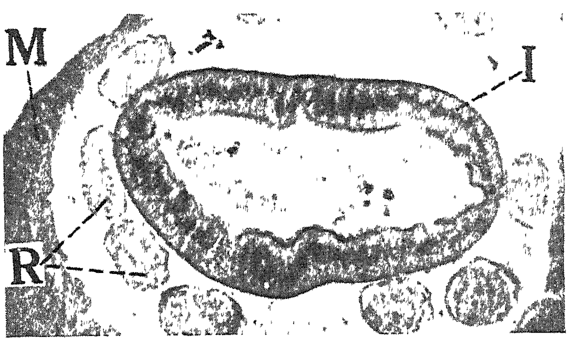

Fig. 1.

Using the usual silver nitrate–acetic acid technique (for the validity of which see Barnett and Bourne[1]), we have investigated the localization of vitamin C in the tissues of *Belascaris marginata*. In specimens taken from dogs fed on a normal mixed diet, we have shown that a large aggregation of vitamin C can be demonstrated in the walls of the intestine. Fig. 1 shows part of a transverse section of Belascaris stained

by the silver technique. The impregnated granules are localized almost exclusively in the intestinal cells (I), whereas the muscular tissues (M) and reproductive organs (R) contain only very minute and scattered grains.

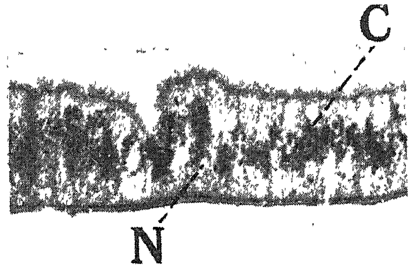

Fig. 2.

The intestinal cells are shown enlarged in Fig. 2. The deposit (C) is typically in the form of approximately spherical granules concentrated close to the nucleus (N) towards the pole nearest the lumen of the gut. It is evident, from these observations, that the parasite can absorb considerable quantities of vitamin C from the food of the host. In this way, it seems likely that the whole vitamin C metabolism of the host may be upset by the presence of the parasite. Thus it may be that in the case of heavy infections especially, absorption of vitamin C by the parasite might be sufficient to cause deficiency effects in the host. Further investigations in cases of infected hosts kept on normal and scorbutic diets may provide some interesting results.

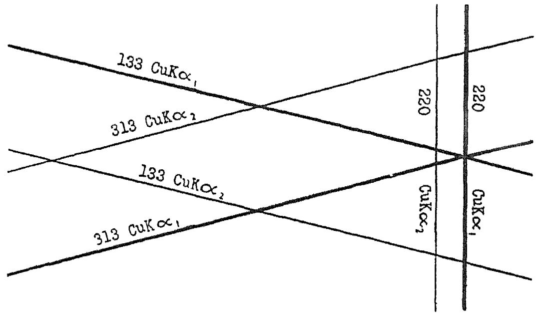
Divergent-Beam X-Ray Photography

IN a recent communication[1] I described a simple way of taking photographs of single crystals using a widely divergent beam of X-rays, and suggested possible uses for this method.

Further study has shown that the patterns obtained from cubic crystals provide an accurate and easy way of determining the positions of the symmetry elements in crystals of unknown orientation. All that need be known is the orientation of the crystal specimen relative to the photographic plate or film. The directions of the symmetry elements are obvious at a glance on the photograph, and can be measured with ease. This is possible even if the specimen contains more than one individual.

The examination of a considerable number of diamonds has shown that divergent-beam photography with copper radiation provides a quick method of selecting type II or good type I diamonds. Type II diamonds (transparent beyond λ 3000 in the ultra-violet, and showing no extra spots or streaks on a Laue photograph apart from the usual thermal spots) give a pattern in which deficiency and reflexion (white and black) lines stand out very clearly indeed against the grey background obtainable in an exposure of a few seconds. Good type I diamonds (opaque beyond λ 3000, and giving reasonably intense groups of extra



spots and streaks on Laue photographs) give extremely bad divergent-beam photographs. The lines, when they can be seen, are very sharp, but they are barely discernible against the background. Incidentally, I have found that although out of some five hundred diamonds examined quickly with a small direct-reading spectroscope and good ultra-violet source, only one was obviously transparent beyond λ 3000, not many (6 in 28 tested) of the apparently normal 'opaque' variety gave really good type I Laue photographs. In those that did, however, the correlation between *good* extra spots and *bad* divergent-beam photographs was very striking. Although the significance of the extra spots of non-thermal origin is still obscure, a reasonable explanation of the difference between the divergent-beam photographs of the two types may be given if, as has been generally supposed, the type I are comparatively 'perfect', or, at least, monolithic in structure, and the type II are 'mosaic'. Ordinary organic crystals, such as anthracene or benzil, give quite good divergent-beam photographs.

The method has also provided a very precise determination of λ/a (X-ray wave-length in the crystal/lattice-constant) for copper $K\alpha_1$ radiation and diamond. It happens that one point of intersection of the 313, 133 copper $K\alpha_1$ conics lies very nearly on the 220 copper $K\alpha_1$ conic. The angular separation of the two is given by

$$\left[\sin^{-1}\sqrt{2}\,\frac{\lambda}{a} - \tan^{-1}\frac{2\sqrt{2}}{3} + \cos^{-1}\frac{19}{2\sqrt{17}}\cdot\frac{\lambda}{a}\right],$$

which leads to the value $\lambda/a = 0{\cdot}431889$ for exact coincidence. On my enlarged photographs the $\alpha_1 \rightarrow \alpha_2$ separation for the 220 reflexion is about 4 mm. and the distance from the (313, 133) intersection for α_1 to the corresponding intersection for α_2 is about 6 cm. A change of lattice constant of 1 in 70,000 (0·05 X.U.) moves the point of (313, 133) intersection by about 0·25 mm. relative to the 220 line, and this is easily observable by eye. Since the method is a null one, depending only upon the almost exact coincidence of two directions in space, one of which varies rapidly with variation of λ/a, it is singularly free from any possibility of experimental error. There are no measurements that cannot be made with any ordinary ruler, and no fine adjustments to go wrong. The diamond can be orientated anyhow relative to the photographic film, and the exact crystal → film distance is immaterial, so long as the relevant 'coincidence' comes within the range of the photograph. Full details of the method will be published elsewhere.

The value of λ/a given above leads to a lattice-constant of 3·55974 kX. if the wave-length of copper $K\alpha_1$ *in vacuo* is taken as 1·537395 kX. and the refractive index for diamond as 0·999989. Individual diamonds have been found to have lattice-constants

varying over a range of about 3·55970 ± 0.00020 kX. (at 18° C.), the limits of error for any one diamond being ± 0·05 X.U. (1 kX. = 1000 X.U.). The upper limit of my measurements (3·55990 ± 0·00005 kX.) was found for a diamond which had been so blackened by heat-treatment that it was almost opaque; although its Laue photograph showed also the powder lines of graphite (the graphite flecks extending throughout the volume of the crystal) it remained nevertheless a good single crystal of diamond, type II. The lattice constants of the two types of diamond showed no consistent variation.

Secondary Non-Laue Reflexions from Phloroglucine Dihydrate

DR. LONSDALE[1] found a type of non-Laue reflexion from diamond which is different from the usual type of diffuse spots, and she mentions them as secondary extra reflexions. The spots of this type are, as distinguished from the primary type, extremely sharp for a special orientation of the crystal with respect to the incident beam, and may occasionally be drawn out into streaks as the crystal deviates from this orientation. Non-radial streaks in monochromatic X-rays have also been found by Lonsdale and Smith[2] in the case of benzil.

In a rotation photograph of phloroglucine dihydrate crystal about its c-axis, it was found that continuous streaks appeared connecting the spots on row lines. On oscillating the crystal through narrow angular ranges, these streaks became more prominent, but they appeared as broken short lengths corresponding to the range of oscillation. The very slow falling off of intensity along the lengths of these streaks indicated clearly that superposed on the regular crystal lattice there was an effect showing a breaking up of lattice along the c-axis, while along the a and the b axes the crystal was perfectly regular. That is equivalent to saying that, in the Laue equations: $a_0(\alpha_0-\alpha) = h\lambda$, $b_0(\beta_0-\beta) = k\lambda$, and $c_0(\gamma_0-\gamma) = l\lambda$, the first and the second equations remain true, while in the third there is a randomness superposed on the regular periodicity along c. Hence if one takes a Laue photograph with X-ray beam incident along the c-axis, one would expect to obtain cross-grating diffraction spots. This was indeed found on taking such a photograph. Actual calculations showed that the positions of these diffraction spots agreed accurately with those obtained from the first two Laue equations for both the copper $K\alpha$ and copper $K\beta$ radiations (except when $h = 0$ or $k = 0$), and these are extremely sharp, in fact showing the exact shape of the irradiated crystal. Laue photographs with the X-ray beam along b and c directions also confirm this breaking up of the periodicity along the c-axis alone.

These diffraction effects occur over and above the ordinary diffuse reflexions, which are much weaker than is usual for organic crystals, except that the reflexion corresponding to the plane (201) is very strong.

It is very remarkable that the central parts of these secondary spots are quite clear. That this is a real effect has been proved by using a number of different crystals of various sizes and from different crops. This clear centre is not present, however, in the case of the Bragg reflexions, either from oscillation photographs or Laue photographs, or in the case of primary extra reflexions. That the secondary reflexions are produced by the outer parts of the crystal and not by the central portion has been substantiated by taking a Laue photograph from a crystal cut along a diagonal as well as by allowing a very narrow beam to be incident on the central part of the crystal only. In the former case, the secondary diffraction spots are of a triangular shape with the middle of the side corresponding to the cut diagonal clear, while in the latter case these spots completely vanished.

Abnormal Dissociation in Flame Gases

SOME experiments have recently been made with a flow calorimeter consisting, essentially, of a vertical water-jacketed tube fitted with a burner the height of which could be varied at will. Two similar resistance thermometers, one consisting of a plain platinum-rhodium wire and the other a quartz-coated wire, each being of the same overall diameter of 0·0005 in., were placed side by side in the gas stream. The products from the flame could be cooled to any required extent before passing the wires by raising or lowering the burner.

The results of a series of experiments with the burner at different heights to give different degrees of cooling of the flame gases are shown in the accompanying table. The mixture supplied to the burner was 25 per cent carbon monoxide plus 75 per cent air in all cases.

Experiment No.	Distance of burner to wires (in.)	Approximate time for gases to reach wires (sec.)	Quartz-coated wire temperature (° C.)	Plain wire temperature (° C.)	Difference in temp. of two wires (° C.)
1	1·5	0·2	1020	1180	160
2	3·5	0·4	960	1080	120
3	5·5	0·7	870	980	110
4	7·5	0·9	800	870	70
5	9·5	1·2	730	770	40
6	13·5	1·6	570	570	0
7	17·5	2·1	420	420	0

It will be noted that there is a marked difference in the two temperatures, the plain wire consistently giving the higher value. This is clearly due to the phenomenon of abnormal dissociation[1]. The interesting fact, however, in these experiments is that the difference in the temperatures recorded by the two thermometers persists until the gas temperature is reduced to about 500° C. This corresponds to the lapse of about 1½ sec. after combustion.

Thus it is established that abnormal dissociation can persist in flame gases when they have been subjected to considerable cooling.

The exact time and temperature at which the two thermometers will record the same temperature, thus

showing that abnormal dissociation has been eliminated, will no doubt be dependent on the geometry of the calorimeter, since this will govern the degree of contact of the flame gases with surface.

A New Technique for the Ultimate Microanalysis of Organic Compounds

WE are grateful to F. B. Strauss[1] for the interest he has shown in our paper on the above subject[2], and for his trouble in giving the list of references. Our statement to which he refers was ambiguous, but this was due to editorial reduction to economize paper. In our original manuscript we stated: "We originated this unpacked tube technique for the ultimate analysis of coal. . . . So far as we are aware this was the first time it had been demonstrated that carbon and hydrogen in organic compounds could be determined by combustion in an unpacked tube. . . . we have now sought to apply our technique to the micro scale." This was altered to the form referred to by Strauss, to which we did not object since the ultimate analysis of coal is taken to imply principally the determination of carbon and hydrogen, and it has been customary to include the sulphur determination with the proximate analysis[3].

All except two of the references given, namely, those of Warren[4] and Marek[5], deal with the determination of sulphur alone, and we were fully cognizant of this work. Indeed, some of it was the basis of our present work, although in our original paper[6] we referred chiefly to its technical application by Vita[7] and Seuthe[8], who based their work on that of Mixter[9]. Presumably, Schöberl's paper[10] is the micro method referred to by Strauss, since all the other references deal with macro methods. It should be pointed out that because sulphur can be determined successfully by combustion in an empty tube it does not necessarily follow that carbon and hydrogen can be. Indeed, Mixter[9] states that in his determinations on tobacco and coal respectively, a small amount of hydrocarbon gases and a small amount of tarry matter passed over unconsumed. In addition, ter Meulen and Heslinga[11] state that in their determination a slight deposit of soot which is difficult to avoid is no serious detriment provided all the sulphur is burnt to sulphur dioxide. It would appear, therefore, that it is possible to get complete sulphur recovery without perfect combustion, and therefore our investigations on the determination of carbon and hydrogen were undertaken.

The papers by Warren[4] and Marek[5] do deal with the determination of carbon and hydrogen, and we are glad to learn of them. It is of interest to examine the differences in technique compared with ours. Warren used a combustion tube packed with asbestos for a length of 10–12 in. and, moreover, recommended that a layer of copper oxide should be placed before the asbestos; so his method can scarcely be said to use an unpacked tube. Marek's work is of greater interest since he does appear to have achieved some remarkably accurate analyses using an unpacked tube. However, he admits that most of them were obtained using a platinum contact, which he somewhat naïvely says was not used because of its catalytic powers but to prevent possible explosions and also as an indicator of the course of the combustion. Thus neither of these workers recommend the use of an unpacked combustion tube.

Two New Carbonyls: Copper and Tellurium

WE are able to report the isolation of copper carbonyl, which we obtained from the reaction of carbon monoxide with heated cuprous oxide. It is a white, readily sublimable solid, the vapour of which is dissociated at a higher temperature with the consequent deposition of metallic copper. Only small quantities are formed, but enough has been collected to afford a preliminary analysis indicating $Cu(CO)_3$ as the empirical formula. A polymeric form would be expected in the case of copper, and its properties suggest that it is very possibly dimeric.

The copper mirrors obtained by Bertrand[1] and by Zelinski[2] by treating cupric oxide with carbon monoxide were thus probably correctly explained by them as due to a carbonyl. No record appears of any attempt by either author to separate the substance. Presumably the oxide contained some cuprous oxide, for we found that cupric oxide did not respond to carbon monoxide, and here we are in agreement with the findings of Mond and Heberlein[3]. From this and other work, Mond and Heberlein concluded that copper does not form a carbonyl. However, Boomer, Martin and Argue[4], using a catalyst made of equal parts of copper, aluminium and zinc in methanol synthesis, obtained an aqueous condensate which, after effervescence, precipitated a yellowish solid believed to be a hydrated copper oxide. In any event, copper was the only metal present. Special interest is attached to the observation because the more effective the catalyst the more the copper removed, as though an intermediate volatile copper compound, possibly a carbonyl, were the active agent. The volatile compound was not further characterized.

We have obtained tellurium carbonyl by the action of carbon monoxide on tellurium. The yields in this case, too, have been very small, but it has been shown to be a gas, and a comparison of its physical properties with those of selenium carbonyl, first isolated in these laboratories[5], and carbonyl sulphide make it clear that its formula is COTe. As expected, it has proved less stable than carbonyl selenide.

Details of these investigations will be published elsewhere.

Ice-Crystal Haloes

A NOTE in NATURE of March 13, 1943, p. 300, reported the occurrence at Bournemouth of what was interpreted as the arc of contact to the 46° halo. Without complete data positive identification of the arc in question is not possible, but it is far more likely to have been the common circumzenithal arc.

The circumzenithal arc is formed by refraction through the 90° angles of ice prisms floating with their axes of symmetry vertical (Fig. 1). Because their orientation is fixed except for freedom to rotate about the axis of symmetry, this arc is well coloured ; it may be faint, but the colours are always relatively pure, in sharp distinction from those of the other arcs and rings.

The true upper contact arc to the 46° halo depends for its formation upon a predominance of crystals floating with a 90° refracting edge horizontal (Fig. 2). As these prisms are otherwise randomly disposed the colours must be broken, and the arc will appear brownish-red.

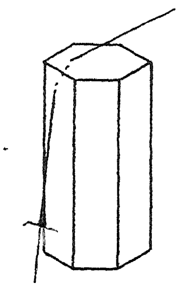

FIG. 1.

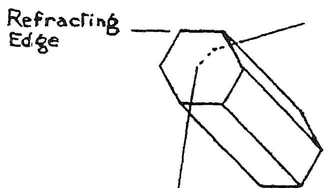

FIG. 2.

The conditions for the formation of the circumzenithal arc are readily fulfilled by the presence of umbrella-like crystals consisting of a flat plate on top of an elongate prism, or of prisms pyramidal at the lower end and hollow in the centre. It is difficult, however, to visualize the type of crystal that would give rise to the contact arc, which, if reliable records were available, might prove to be as rare as the parhelia to the 46° halo.

The mention of colour in the Bournemouth arc, the low sun at 4 p.m., February 8, the lack of mention of any 46° halo, and the commonness of the circumzenithal arc, make it reasonably certain that the latter was the arc in question. This arc may be expected any time that parhelia to the 22° halo occur with a solar altitude of less than 32°, provided that the cirrostratus sheet extends overhead.

My observations for the year ending October 15, 1943, may give some idea of the relative commonness of the better-known ice-crystal phenomena :

22° halo	190 days
Parhelia to 22° halo	38 days
Circumzenithal arc	13 days
Sun pillar	9 days
Circumscribed halo of 22° halo (including contact arcs, that is, incomplete halo)	8 days
46° halo	6 days
Horizontal or parhelic circle	5 days

It may be noted that the rainbow was seen on four days in this period and the fogbow (white rainbow) once. These and earlier records show that some of the ice-crystal phenomena are considerably commoner locally than is the rainbow. The fact that many people have never seen even the 22° halo is partly due to a disinclination to look close to the sun or high in the sky.

In three years of consistent observations I have seen Lowitz' arcs four times, and a 19° halo, the counter-sun and the parhelia to the 46° halo once each. The last two were part of a beautiful display already described[1]. I have yet, however, to see the contact arc to the 46° halo.

From 15° to 25° solar altitude the circumzenithal arc is virtually tangent to the large halo, but outside this range it quickly departs from it. The confusion of these arcs is widespread, and is even revealed in the records published by Pernter[2]. The distinction is emphasized by Minnaert[3], whose fascinating book is recommended to the interested reader.

Grey Mould (*Botrytis cinerea*) of Flax

IN the course of the examination of large numbers of samples of flax seed by the Ulster method[1] for the presence of seed-borne parasites, many were found to be contaminated with *Botrytis cinerea*. As in some of the samples more than 25 per cent of contaminated seeds was recorded, the pathogenicity of the isolate from home-saved seed was investigated, since *B. cinerea* is known to cause grey mould of flax.

Seeds from a sample known to be free from any known parasite were dipped into a suspension of spores prepared from a pure culture of *B. cinerea* isolated from flax seed. The inoculated seeds were sown in pots of moist sterilized soil which were then covered with sterile bell jars. A few days after the appearance of the cotyledons a number of seedlings produced from inoculated seeds showed brownish-coloured lesions on the hypocotyl at about soil-level ; these seedlings afterwards developed the typical symptoms of 'damping off'. Conidiophores first appeared on that portion of the hypocotyl which was originally attacked, and within a short time spores were produced on all aerial parts of the dead seedlings. No difficulty arose in making isolations of the causal organism from the hypocotyls of seedlings showing early symptoms of attack. Seedlings in control pots sown with uninoculated seeds remained healthy provided the covering bell jars were not removed. The experiment was repeated using spores from isolates from diseased seedlings, and similar results were obtained. The work was carried out in an unheated greenhouse during the summer.

Van Poeteren[2] investigated the control of grey mould by seed disinfection and obtained good results.

The efficacy of those seed treatments which were found to give a good measure of control of other seed-borne diseases of flax in Northern Ireland[3] was accordingly tested. The effectiveness of each treatment was determined in the laboratory by the modified Ulster method[4], five hundred seeds being examined in each case. Treatment with 'Nomersan' at the rate of 12 oz. per cwt. of seed or with 'Ceresan U564', using an 8 per cent solution at the rate of 0·9 gal. per cwt. of seed, reduced the contamination of the seed with viable *B. cinerea* from 15·0 per cent in the control to 0·4 and 1·4 per cent respectively in 1942 and from 13·1 per cent (control) to 1·2 and 1·6 per cent respectively in 1943. Organo mercurial powders applied by the 'fixation' method of seed treatment were not so effective.

In pot experiments made both in the greenhouse and under an open outdoor verandah very satisfactory control of the disease was obtained by the use of both 'Nomersan' and 'Ceresan U564'. In field tests 'Ceresan U564' was very effective, 'Nomersan' also giving good results. Unfortunately, in the field trials made in 1942 the development of the disease was almost completely checked at a very early stage by the onset of cold dry weather, and the yield of fibre was not influenced by treatment. In a similar field trial in 1943 the disease did not appear even in the control plots, probably due to the cold weather which followed sowing.

Observations made in the field show that *B. cinerea* can attack and kill portions of stems of mature plants, and that it is often present on the stems and capsules of plants if prolonged periods of damp weather occur after the crop has been pulled.

Future of Anthropology

PROF. LE GROS CLARK[1] takes exception to remarks which I made in reporting a discussion on the future of anthropology at the recent centenary meeting of the Royal Anthropological Institute. The point at issue concerns the scope of physical anthropology. It would be generally agreed, no doubt, that this is a practical question concerning the convenience of study rather than an attempt to frame a logical definition of a subdivision of science.

Prof. Le Gros Clark refers to his presidential address to Section H of the British Association in 1939. In this he adopts the commonly held view that physical anthropology is concerned with the evolutionary history of man. This is a historical theme though it embraces the study of existing populations. Contact is made with the activities of students who are concerned with living peoples but who have no special interest in any historical theme. It is clear that research in this field cannot be divided into a number of separated compartments. It should all be related and interdependent, however various the approaches may be.

In the communication referred to, the physical anthropologist is urged to study "comparative racial physiology". His subject, we are told, should be *completely* re-orientated "along functional lines", its *main* concern (the italics are mine) being the study of physical efficiency in "native populations", with reference to all factors which influence it—such as inborn differences, nutrition and other environmental conditions—and all other relevant kinds of evidence, including medical and demographic statistics and the application of various physiological and other tests. But why restrict the scope of such inquiries to native populations, since anthropology is concerned with the whole of mankind ? Are its students also expected to carry out research on the same lines for all "advanced" populations as well ?

It is clear that research of the kind referred to is needed, and that its results would be of interest to physical anthropologists. The question is whether they can be expected to consider that problems of the kind referred to should be their special concern. If they do, then the diversion of their very limited resources—at present almost non-existent in Great Britain—must entail neglect of 'academic' physical anthropology. Alternatively, it may be supposed that researches into the social biology of any kind of society can be more properly considered the concern of other workers, whether they be called social biologists, or eugenists, or something else. They might well urge that investigation of the questions involved, which are of immediate practical importance, should be undertaken by the State and not left to university workers.

Prof. Le Gros Clark exclaims at the suggestion, which he incorrectly attributes to me, that physical anthropologists cease to be such if they deal with practical problems. I should say that in so far as they do so, they are serving the 'applied' rather than the 'pure' interests of their science. Zoologists are not expected to be specialists in animal husbandry.

Mathematics as a Cultural Subject

THE plea in the editorial in NATURE of November 13 on "Science as an Educational Discipline" will find a warm welcome from those who have been concerned with spreading an understanding of the broad significance of science for modern society as well as the details of particular parts of science. Paying less attention to sharp division of science into different subjects and more to the interrelation of these subjects, the history and development of our great heritage and the social possibilities which it holds forth will help to spread a better appreciation of what science stands for among the population at large.

Here I would like to urge that mathematics should also be treated from the same point of view, and should not be put on one side as though it were totally different. The conventional approach to the subject only too often seems to make it appear mysterious, esoteric and external to the pupil's experiences. Without a clear understanding of what mathematics can do and what it cannot do, then it is very easy to be misled by all kinds of arguments using quite unjustifiable mathematical proofs. If mathematics is linked up more closely with the physical sciences, then it is possible to explain the significance of such developments as the calculus and graphs, and to

show that they represented a real advance for mankind instead of merely examination examples; the exaggerated emphasis on plane deductive geometry will give place to a better understanding of the spirit of mathematics. Judging from the school syllabuses, one would imagine that every mathematician was continually using logarithm tables, whereas the present tendency is more and more to use machines both in commerce and in research laboratories.

It is not possible, however, to estimate correctly the importance of mathematics if it is only considered in relation to the physical sciences. Mathematics is very closely related to both the natural and the social sciences, although so far in history the main impetus for its development has come from the former; this is mainly because society hitherto has been much more interested in the natural sciences because of their immediate importance in technology. Nevertheless, statistics owes its development to the social sciences. Even at quite an elementary level, a proper treatment of averages brings in ideas which are not common to other parts of mathematics and which are important in the world to-day. During the War, increasing use has been made of the methods of pictorial statistics in order to make numerical results more understandable.

Lastly, it should never be considered that greater emphasis on these broader aspects of mathematics and science is only of value to the 'man in the street' and not to the expert. To-day we are meeting all kinds of interconnexions between apparently unconnected parts of science, and the person who specializes on one narrow section without appreciating its relation to the whole of modern knowledge is apt to take longer in his work and not see its true significance when completed.

Chard,
Somerset.

Area Heating

HAVING been responsible for many large district heating plants on the Continent, I have read with great interest the article "Area Heating" in NATURE of October 30. It is often said that in Great Britain, with its mild climate, there is no need for district heating. The ever-increasing number of central heating plants, however, shows the urgent demand for centralized, labour-saving heat supply; and by the adoption of district heating, relatively more coal can be saved in Britain than on the Continent. By co-ordination of heat and electric-power generation, it will be possible to reduce the present consumption of coal for heat and electric power generation in towns and cities more than by half, and to eliminate entirely the smoke nuisance with all its evil effects.

The co-ordination of heat and electric power generation is, however, a more complicated and difficult matter than it appears to be from Dr. Hughes's article. The thermal efficiency of electric power generation from steam greatly depends upon the vacuum, and the cooling water is heated in the condenser to a temperature of 85°–100° F. only, which is of no use for heating purposes. Higher temperatures can only be attained by an increase of the back-pressure, and this is accompanied by a corresponding increase in steam consumption for electric power generation. A further difficulty is that the hourly, daily and seasonal variations of the heat and electric power loads do not coincide. The daily variation can be overcome, as Dr. Hughes rightly pointed out, by hot-water storage, but this method is not applicable for seasonal variations.

According to Dr. Hughes, after the War new electric power stations will be required. Should it be the case, it would be better, from the point of view of district heating, to install the new generating capacity in existing stations as back pressure sets for heat and electric power generation. This will give a much greater flexibility for development of district heating than new large heat electric stations.

The suggestion of Dr. Hughes to burn the coal in new boiler stations located on the rim of large centres of population and to transmit the steam to turbo-generators located at the centre of gravity, disposing of the heat in the surrounding domestic and industrial areas, is probably due to a misapprehension. In my paper before the Institution of Heating and Ventilating Engineers[1], I showed the possibility of electric power generation in two, or even three, pressure stages when co-ordinated with district heating. In the primary station, steam of high pressure is used for electric power generation with back pressure sets, and the steam of, say, 200 lb. per sq. in. abs. is transmitted to the older station to feed the back pressure sets for electric power and heat supply. Thus the boiler house can be eliminated and generation of electric power and heat is made possible inside a town without the burning of coal. The steam from the primary station must, of course, be delivered to the secondary station with sufficient superheat. Therefore, the steam main must be carefully insulated to reduce the loss of the valuable superheat as much as possible. But even mains carrying low-pressure steam or hot water and accumulators have to be carried out with good insulation. Owing to the increased transmitting capacity, the percentage of heat losses of large mains is very small. The actual heat losses and their costs, however, are practically proportional to the area of the pipe surface. The economic thickness of the insulation has, of course, to be calculated for every scheme, but it has generally been found that good insulation pays.

The saving in fuel was the main argument for the introduction of district heating in the U.S.S.R. That country is now leading in the development of district heating, and the new electric power stations are already predominantly built for co-ordinated heat and electric power supply.

A. E. MARGOLIS.

12 Caxton Street,
London, S.W.1.

[1] "Experience with District Heating in Europe and U.S.A. and its further Development". *J. Inst. Heat. and Vent. Eng.* (November 1935).

I AM particularly glad that Mr. Margolis has been prompted to publish more relevant information on area heating, and to correct some of my speculations based on the technical data already available. I certainly did not intend to convey the idea that area heating could be effected from existing plant. I agree that the location of boilers at a distance from the generating station is probably uneconomic, but if the advantages to a community are sufficiently recognized, maybe the community might sanction the excessive cost.

L. E. C. HUGHES.

RESEARCH ITEMS

Genes and Development

IN two papers, H. Grüneberg (*J. Genetics*, **45**, 1–22, 23–29; 1943) describes his recent work in analysing the manner in which genes causing abnormalities in the mouse exert their influence. A recessive gene *ch* results in the development of hydrocephalus, but the most interesting point is that the final effects of the gene are due to anomalies in the early development of cartilage. As a result of the aberration in cartilage development, there is a shortening of the basi-cranial cartilage and nasal septum. This gives rise to a dorsal bulging of the cranial hemispheres. The lower part of the brain is compressed and interferes with the normal drainage function of the foramen of Magendie; hence hydrostatic pressure is increased. The bulge thins out the osteogenic membrane and prevents the formation of the membrane bones. Strain on the blood sinuses leads to internal hæmorrhage, while skin strain gives rise to other anomalies. These various pleiotropic effects are thus shown to be secondary effects of the cartilage anomaly. Grüneberg claims that pleiotropism does not exist, but that a gene produces only one chemical reaction; and there is no reason to suppose that genes have more than one action. The gene, says Grüneberg, is cell- or tissue-specific and never organ-specific in action. He suggests five postulates for the analysis of gene action, which include biochemical and morphological methods. In the second paper Grüneberg describes two further mutants in the mouse—fidget and hydrocephalus—which present interesting features for similar developmental studies in the future.

Development in Drosophila

C. H. WADDINGTON (*J. Genetics*, **45**, 29–44) and C. H. Waddington and R. W. Pilkington (*J. Genetics*, **45**, 45–50; 1943) describe the effects of several leg and eye genes respectively in *Drosophila melanogaster*. The obvious effects of the leg genes dach, dachous, comb-gap and four-jointed are seen in the foreshortening of the legs, but they also affect other parts of the body. In combination, there is found additive effects and exaggeration phenomena in different organs in an apparently inconsistent series. Waddington considers that the explanation should be sought in the effect of the genes upon the folding of the imaginal buds. Where abnormal folding of the buds takes place by aberrant growth, the succeeding abnormal histogenesis will give rise to the various pleiotropic effects. Indeed, X-ray radiation of the imaginal buds during their growth gives similar abnormal folding and similar manifestations in the characters. Waddington and Pilkington have traced the development of eyes of Drosophila carrying the genes facet, lozenge-spectacled, ophthalmopædia and morula. Several remarkable divergences from normal development are described. The authors consider that, as in the work described in Waddington's paper, the genes disturb the method of folding of the imaginal buds.

Wheat-Puccinia Relationships

ALTHOUGH the haustoria in *Puccinia graminis Tritici* penetrate the cells, they remain external to the protoplasts, and the latter can be plasmolysed independently of the haustoria, which themselves are plasmolysed by solutions with concentrations 3–4 atmospheres higher. This aspect focuses renewed attention on the permeability of the host cells, as in a recent paper (Thatcher, F. S., *Canad. J. Res.*, C **21**, 151; 1943). Haustorial invasion always seems to be accompanied by an increase in the permeability of the host cell, often to the extent of being fatal. Treatment of plants with chloroform vapour, which increases the permeability of the protoplasts, leads to a lowering of resistance. Cold hardening, which also increases the permeability of the host cells, in some cases lowers the resistance, but this effect is probably offset by the increase in osmotic pressure induced at the same time. When the wheat variety Kubanka is grown at 80–85° F., the increase in permeability of the host protoplasts caused by the higher temperature seems to be the cause of the rapid early growth of the fungus—later the host protoplasts appear to have an adverse effect on the parasite, since just before they die they cause the formation of brown walls round the haustoria and a kind of encystment. This results in the 'browning reaction' characteristic of Kubanka when grown at high temperatures. Certain varieties, which appear to occupy a threshold position between resistance and susceptibility, give an 'x' or 'mesothetic' reaction with certain races of *Puccinia graminis Tritici*. Infection rapidly leads either to pustules or resistant brown flecks, often both on the same leaf. Host cells from pustule and fleck areas showed higher and lower permeabilities respectively than did those from normal healthy areas. The mature resistance of Hope wheat may be due to its possession of a low water availability to the parasite—seedling leaves have a higher permeability and are less resistant than mature parts. The susceptibility of the host to rust is not modified by previous infection with smut, neither in oats, barley and maize nor in wheat.

Mineral Deficiencies in Fruit Trees

Two recent papers add to our knowledge about mineral deficiencies of fruit trees (*J. Pom. and Hort. Sci.*, 20, Nos. 3 and 4; 1943). J. B. Duggan (pp. 69–78) has succeeded in restoring the green colour to the leaves of cherry trees which were chlorotic through manganese deficiency. This was accomplished by injecting solid manganese sulphate into large branches and into the trunk. Neither injection nor spraying with solutions of the salt was satisfactory in practice. The deficiency of manganese was established by spectrographic analysis of the leaves. D. W. Goodall investigated the intake of calcium, iron, magnesium, manganese and potassium into the apical, middle and basal leaves of various kinds of shoot and spur of the apple Cox's Orange Pippin. He found that intake of the various ions varied with manurial treatment. Samples from plots receiving sulphate of ammonia, for example, contained 42 per cent more manganese than from the plots without added nitrogen. Differences in the manganese and potassium status of different trees are reflected more clearly in the composition of the basal leaves of the fruiting spur than in that of other leaf types.

New Methods in Plant Breeding

DELPHINIUM species and varieties are diploid, tetraploid or hexaploid. Intercrossing between these groups will naturally lead to sterility if the hybrid is obtained. *D. cardinale* is a diploid species with a distinctive scarlet colour. G. H. L. Mehlquist, C. O. Blodgett and L. Bruscia (*J. Hered.*, 34, 187; 1943) have used several methods of applying colchicine to

this species and have obtained tetraploid derivatives. These have been used in crosses with commercial tetraploid varieties of *D. elatum*, to introduce the scarlet colour and the high resistance to Erysiphe (powdery mildew) of *D. cardinale* into existing varieties. So far a few hybrids have been obtained, but many more can be expected.

Forms of Phosphoric Oxide

IT has long been known that phosphoric oxide (P_2O_5) exists in different crystalline and glassy forms. W. L. Hill, G. T. Faust and S. B. Hendricks (*J. Amer. Chem. Soc.*, 65, 794; 1943) have made a study of the preparation and identification of the different modifications, measurements of their optical constants, the phase transformations by the quenching method, and an interpretation of vapour pressure data. They conclude that there are three crystalline forms: hexagonal, rhombic and a stable (probably tetragonal) form, as well as a glassy form. The system involves three triple points at which solid, liquid and vapour (P_4O_{10}) co-exist in equilibrium, and there are at least two distinct liquid forms, one a stable polymer of the other, which were identified with the melting of the stable and hexagonal forms, respectively. Some X-ray data are given for the three solid forms. The stable form can be superheated above its melting point.

Bonded Deposits on Economizer Heating Surfaces

IN a paper on this subject read recently in London by J. R. Rylands and J. R. Jenkinson before a joint meeting of the Institution of Mechanical Engineers and the Institution of Electrical Engineers, it was pointed out that the problem of boiler plant availability in power stations has become so prominent that a better understanding of the causes of the fouling of heating surfaces by deposits from the products of combustion is essential. Earlier theories based on fused ash particles, sodium sulphate bond or high dew-points have not satisfactorily accounted for various well-established facts of observation. The latter include the existence of a period of apparent immunity from deposits in a new boiler plant, the characteristic behaviour of the dust from pulverized fuel firing and the peculiar scale-like form of certain hard deposits occurring on economizer and boiler tubes. The authors have found that hard bonded deposits on economizers result from certain chemical reactions between fuel dust and sulphuric acid. The type of reaction depends on the temperature of the metal parts associated with the deposits. Practical suggestions for the prevention of hard bonded scale formation in economizers are made, various types of coal ash being discussed, and characteristics favouring bonded deposit formation pointed out. The influence of the authors' proposals on plant design is considered.

Solar Prominences

AN important paper by E. Pettit (*Astrophys. J.*, 98, 6; 1943) deals with the classification of solar prominences according to their association with sunspots, their origin, their motion and their structure. A tentative evolutionary sequence includes prominences of the quiescent, active, eruptive, sunspot and tornado types, and a new type, the coronal prominence, is distinguished. A comparative description of each type is given, and subdivisions of many of the classes are illustrated by diagrams and photographs. The paper forms a valuable summary of the results obtained by the assiduous study of the solar surface at the Yerkes and Mt. Wilson Observatories during the past two decades.

Multi-Colour Photometry of Stars

A NEW photo-electric photometer for stellar work has been recently brought into use at the Mount Wilson Observatory, and is now described by J. Stebbins and A. E. Whitford (*Astrophys. J.*, 98, 20; 1943). With the 60-in. reflector, measurements can be made in a spectral range as wide as 3530–10300 A. on stars as faint as the ninth magnitude. The photocell used is of the cæsium oxide type and is especially sensitive to red radiation. A series of filters enables measurements to be made at six points from the ultra-violet to the infra-red. The instrument was designed to measure the colours of faint extended sources such as the nebulæ, but some results on stars incidental to the main programme are now published because of their intrinsic interest. These concern the colours of 69 stars of types *O* and *B* showing various degrees of reddening by interstellar absorption. Small deviations are found from the λ^{-1} law of reddening, in the sense that the radiation is fainter in regions intermediate between the ultra-violet and infra-red, but the law is the same for all directions in the galaxy. Even the simple λ^{-1} law requires *ad hoc* assumptions regarding the size distribution among the absorbing particles, and the deviation found will give further material for study. That the form of the reddening is constant simplifies matters somewhat; evidently equilibrium has been reached and the interstellar cloud must be regarded as a permanent feature of the galaxy.

Determination of Time Corrections

THE Astronomical Institute of Sciences of the U.S.S.R. has issued "Ephemerides for the Determination of Time Corrections by Equal Altitudes (Zinger's Method) for 1941". Four quantities for each pair of stars are tabulated, these quantities depending only upon the co-ordinates of stars entering the given pair. The values of the four quantities refer to the moment of upper culmination of a fictitious star over the Greenwich meridian. The right ascension of this star is the mean of the right ascension of the two stars, and the moment of upper culmination is called the moment of culmination of the pair. Tables are given which provide these four quantities in a continuous reckoning through every ten culminations, that is, through ten sidereal days. In the heading of each pair of stars selected are numbers which denote the various working ephemerides, and the names of stars corresponding to the numbers are given in Table IV. Full explanations of the use of the ephemerides are given with examples, and the necessary calculations are very easily effected. In addition, it is shown how the calculations of chronometer corrections are carried out, and these are facilitated by a special table compiled for the purpose. Special attention is directed to the fact that, in computing the long-period terms of nutation, certain terms are omitted which have been newly introduced by some ephemerides, such as the "Nautical Almanac" and the "Berliner Jahrbuch". It is shown that the total effect of these terms on the half-sum of the right ascensions is negligible. The effect of the short-period terms of nutation are easily computed by means of special tables given for the pairs of the ephemerides by Prof. Zwetkoff.

FEEDING WASTE APPLES TO POULTRY

By H. TEMPERTON
National Institute of Poultry Husbandry, Newport, Shropshire

THE domestic poultry-keeper in return for the cancellation of each shell egg registration is entitled to purchase sufficient 'balancer meal' to furnish approximately half the total dry matter requirements to support one laying bird. This specially compounded meal is richer in protein and minerals than would be the case of a ration designed as the sole food for layers, and its composition has been so formulated that when supplemented by appropriate quantities of edible waste, mainly of a carbohydrate nature, from the kitchen and garden, it provides a suitably balanced ration for egg production. During the past three years a considerable amount of experimental evidence has accumulated on the use in poultry rations of surplus or waste products of the garden or allotment.

At this Institute we have received from time to time inquiries from poultry-keepers concerning the nutritive value of windfall and damaged fruits from dessert and culinary varieties of apple and from ornamental crab trees. Correspondence which has appeared in the poultry Press recently lends confirmation to the belief that there are many domestic poultry-keepers with access to supplies of these types of fruit who are uncertain of the advisability of feeding them to their stock. It has been claimed by some that the organic acids present in apples and pears, and particularly malic acid, exercise a pronounced laxative effect which may result in enteritis when appreciable quantities of fruit are consumed by the birds. Bayon[1] discredits this view on the grounds that the organic acids present in the fruit are less concentrated than the free acid of gastric juice. There are no references in the available literature to experimental observations on poultry, but Klimmer[2] makes the general statement that malic, tartaric and citric acids, which occur in the juices of many so-called acid fruits, all aid the digestive processes, promoting the digestion of albumen, and, in the presence of sugar, influencing the solubility and absorption of certain phosphates and other mineral salts which are insoluble in their absence.

The feeding trial which is now described was designed to provide a more factual basis on which to give advice.

The supply of apples used was of two types: (1) a heterogeneous sample of windfalls from culinary and dessert varieties collected from the ground in September and comprising badly bruised and scabbed fruit; (2) fruits picked at the same time from trees of the Siberian crab (*P. malus* var. *sibirica*).

A sample of the crab apples showed on chemical analysis the following percentage composition:

Moisture ..	83·0	*Dry matter*	
Dry matter ..	17·0	Crude protein	5·00
		Ether extract	0·97
		Crude fibre	4·60
		Nitrogen-free extractives	85·63
		Ash	3·80

Owing to the difficulties of obtaining a representative sample no analytical data were determined on the cultivated apples. For the purpose of this qualitative test five parts by weight of either source of apples were considered to provide the equivalent dry matter of one part of meal.

A group comprising ten first-cross pullets were used for the experiment and were housed in individual laying cages in a battery house and fed the following rations (oz. per bird daily):

	First 14 days	Remainder of test
Layers mash	4·0	3·0
Apples	5·0	10·0

The available supply of crab apples only provided for seven days feeding at the higher level and these were used during the fifth week of the test. During the first fortnight apples constituted 55·5 per cent of the gross weight of food eaten. The apples were minced by passing them through a vegetable shredder, and the juice which was expressed was conserved and used to mix the residual pomace and mash into a wet feed. The day's supply of food was provided in one meal given in the morning. No difficulty was experienced in getting the birds to consume the daily quota of food; on the contrary the ration appeared to be markedly palatable. The physical condition of the droppings remained normal and there was no evidence of scouring. After the test had been in progress for fourteen days the daily amount of mash allowed per bird was reduced by one ounce and replaced by a further five ounces of apples, which now constituted 76·9 per cent of the total weight of food offered. The appetite and general health of the birds were unaffected by this increase or by the subsequent inclusion of crab apples in the ration.

The experiment came to an end after forty-eight days, when the available supply of fruit was exhausted.

Experience at the Institute with laying pullets kept in individual cages in a laying-battery and fed an *ad libitum* supply of the particular meal used in the present instance has shown that the average daily consumption has been about 5 oz. per bird. On this basis the use of apples as part of the diet effected over the entire feeding period of forty-eight days a saving of 34·1 per cent of mash, or just over 5 lb. per bird, and constituted 72·1 per cent of the gross daily weight of food consumed. At the conclusion of the tests the average body weight of the birds showed an increase of 9·1 oz. No deaths occurred, and the health of the birds as judged by external characteristics was unimpaired by the rations fed. The short duration and limited scale of the test afford little more than indications of the effects on egg production. Average egg production is not a reliable reflexion, since two birds did not reach sexual maturity until after the test was concluded and others only came into lay towards the end.

The egg yield of individual birds which were in lay when the experiment commenced remained satisfactory and equal to that of similar birds receiving unrestricted access to a balanced laying mash.

The results of the test demonstrate that no toxic effects to laying birds are likely to follow the feeding of substantial quantities of ripe apples of the types used in the present instance. I am, however, not inclined to discredit the claim that under certain conditions the ingestion of apples can lead to pronounced digestive disturbances and impair the health of fowls, since observations have shown that where poultry, and more particularly young stock, have had access to unripe windfall apples these have been

readily eaten and followed by severe scouring. The experiences of youth provide an eloquent testimony of the diverse digestive effects following the abnormal intake of sour and ripe apples.

The disappearance of acidity due to the utilization of organic acids in respiration and in the synthesis of sugars is one of the concomitants of fruit ripening, but it is unlikely that this provides a valid explanation of the physiological disorders caused through eating unripe fruit, since medical experience indicates that the acidity of the digestive tract is entirely dependent on factors influencing the amount of the gastric secretion and its hydrogen-ion concentration.

Archbold[3] has demonstrated that the first stage in the growth-phase of apples following petal-fall is characterized by the formation of cell-wall material, and the intake of nitrogen. It is possible that the toxicity of immature fruit is due to a relatively high content of non-protein nitrogenous compounds, which are regarded as the principles responsible for similar physiological disturbances in larger farm livestock when unripe mangels or large quantities of young grass are suddenly introduced into the diet.

CLEANSING OF MILK BOTTLES

MOST of us have received the familiar wide-mouthed milk bottle with its pressed-in cardboard stopper and, wiping with some anxiety its dirty neck, have wondered whether the milk is fit to drink. Remembering the difficulties of war and aware of the psychologist and his dirt-complex, we have reflected that anyhow the milk in our bottle is all the milk we can get and have tried not to be too fussy about it. The 'authorities', we know, have our cows tested for tuberculosis and do what they can to see that the milk we get is as clean as possible before it goes into the bottles ; the medical men—and some others—wrangle interminably about the obvious advantages of pasteurization ; but may not all these efforts be stultified by inefficient methods of washing, filling and distributing milk bottles ? May not a roundsman who is naturally unaware that he is a typhoid carrier undo all the labours of those who have provided him with typhoid-free milk ?

The first answer to these natural anxieties of the milk consumer is the Milk and Dairies Order, 1926—note the date—which requires that all milk containers and all appliances which come into contact with milk shall be thoroughly washed as soon as may be after use and shall be cleansed and scalded with boiling water or steam before they are used again ; the second answer is that the Ministry of Health, three years before the War, asked for a survey of bottle-washing plants to find out whether treatment of them with caustic detergents was as good bacteriologically as steam sterilization. The results of this inquiry, carried out between October 1937 and July 1939, by G. S. Wilson and Betty C. Hobbs, were given in a full report to the Ministry, a copy of which can be seen at the library of the London School of Hygiene and Tropical Medicine. An abridged version appears in the *Journal of Hygiene* (**43**, 96–120 ; 1943).

Its conclusions can be given only briefly here ; on the whole, they will reassure the householder. They agree largely with the results of similar investigations in the United States. A total of 2,406 milk bottles from 105 washing and distributing plants of 26 different types was examined. Hand washing of bottles is condemned. Small dairies often disregard the Milk and Dairies Order. Steam sterilization is efficient if it is carefully done ; otherwise it is not. But on the whole, equally good results were obtained in large and small rotary plants with either steam sterilization or hot caustic detergent (caustic soda with or without additions). The spray type of washing machine was the best, and the best results were obtained without brushes. Virtual sterility could be obtained with either strong caustic soda at a low temperature or with weak caustic soda at a high temperature, and it is not necessary to change the detergent more often than occasionally, provided that it is brought daily up to strength and that foreign matter is filtered out and deposit in the tanks is removed every few days.

One very interesting result was that no coliform bacilli were found in the washed bottles. The detergent killed these. This would eliminate, in well-conducted plants, milk-borne diseases derived from homes from which empty bottles are returned ; but can we be sure that all plants are conducted well enough to ensure this ? Of the organisms found in the washed bottles about half were saprophytic, one quarter were cocci and one quarter were yeasts, moulds, hæmophilic organisms and aerobic spore bearers. These, like the coliform bacilli, would have been killed by the detergent, so that they must have got into the bottles after they had left the detergent. It was found that most of them came from the rinsing water used to get rid of the detergent, which was heavily contaminated.

United States workers have recommended the use of chlorinated water to remove the detergent and to check the bacteria in the rinsing water, but Hobbs and Wilson prefer a rinse in water at 120° F., followed by cooling by washing the exterior only of the bottles at decreasing temperatures, until a temperature of 70° F. is reached. A final cold spray from the water main over both the outside and inside of the bottle completes their process. If bottles are hotter than 68° F. when milk is put into them, the life of the milk will suffer. Frequent cleaning of the washing machines is, of course, desirable.

To these complex problems of washing and cooling on a large scale must be added the important one of storage of bottles in small plants, where they are kept some hours or even overnight before they can be filled. Bottles should never be stored the right way up. When they are inverted their bacterial content depends on the amount of moisture and the temperature ; in warm damp weather it is likely to be higher.

Householders will be glad to learn that the familiar wide-mouthed bottle with its cardboard stopper is condemned ; it would be more satisfactory if a hooded cap covered its neck. A narrow-necked bottle with a press-over cap, or a bottle with recessed angles, would lessen the risk of contamination of the milk when it is poured over a dirty and frequently handled brim. A paper-board container which is used only once is the ideal, but it is too expensive at present.

The importance of clean milk bottles is shown by reference to the literature on typhoid epidemics and other milk-borne diseases. In the United States, 296 out of 373 outbreaks of typhoid were traced to carriers either on the farms or in the milk-distributing plants.

While we need not, in Great Britain, be unduly alarmed by such figures as these, the fact remains that clean milk is a vital concern of the whole community. If the farmer and the veterinary surgeon do their best to give us clean cows and clean milking, we should see to it that the bottling and distributing organizations do not introduce disease. The householder has an important responsibility too—he should see that used bottles are well washed in hot water before they are returned to the roundsman, especially if there is communicable disease in the house. The problem is complex, requiring, like so many features of our modern civilization, the willing co-operation of all who take part in the chain of operations which link the producer with the consumer. The authors of this paper are to be congratulated on the completion of a very complex and difficult piece of public work. Before they could do it they had to work out methods which are valuable contributions to knowledge.

G. LAPAGE.

PALÆONTOLOGY WITHOUT FOSSILS IN THE 'BIRD-WING' BUTTERFLIES

EVER since the days of the immortal Wallace, biologists have been intrigued with the distributional problems presented by the fauna of the Malay Archipelago. Probably the butterflies have proved more attractive than any other group, not only on account of their æsthetic charm, but also because the pattern and colour of their wings are susceptible to modification by isolation and climate. There is no doubt that Wallace had the butterflies in mind when he wrote in 1869: "It is certainly a wonderful and unexpected fact, that an accurate knowledge of the distribution of birds and insects should enable us to map out lands and continents which disappeared beneath the ocean long before the earliest traditions of the human race".

The latest contribution to this subject is of considerable interest and is described by the author, Dr. F. E. Zeuner, as "palæontology without fossils".* Essentially, it comprises an attempt to reconstruct phylogenetic trees for the 'bird-wing' butterflies on the basis of the morphology of the species-groups and the present distribution, and the evolutionary patterns thus obtained are compared with the geological history of the Malay Archipelago. The more or less complete agreement found between these two methods of approach is highly satisfactory.

In order to obtain the requisite data for an accurate division of the 'bird-wing' butterflies into species-groups, a considerable amplification of previous systematic work on this genus has been necessary, and this has been carried out principally on the basis of the male genitalia. Accordingly, the 'bird-wing' butterflies are divided into two major groups, the *Troides* Hübner + *Trogonoptera* Rippon group and the *Ornithoptera* Boisduval + *Schoenbergia* Pagenstecher group.

The phylogenetic trees for these two major groups are reconstructed on the reasonable assumption that each of the groups of subspecies existing at the present time has been derived from a common ancestral form in comparatively recent times and that, at some earlier period, each of the species-groups present to-day was a subspecies-group, and so on until a stage is reached when there was a common ancestor for each of the two major groups. All the known species of the Troides + Trogonoptera group can be obtained from a single parent-form on the assumption that this division into subspecies which eventually became differentiated into species has taken place at least five times. There can be little doubt that the common ancestor of the essentially western Troides complex originated in Sundaland, that is, in the continental land-mass formed by the union of the Malay Peninsula, Sumatra, Java and Borneo in the Tertiary. The Ornithoptera + Schoenbergia group can also be reduced to a single form on the assumption of five successive phylogenetic waves. While it is clear that the Ornithoptera complex of species has developed in the Papuan area, its past history is by no means so manifest as that of the Troides group for, in its earlier stages, the distribution of Ornithoptera proper was discontinuous, representatives being confined to the Moluccas and the Solomon Islands, while there was an interclave of Schoenbergia in New Guinea.

Regarding the geological history of the Malay Archipelago, it is evident that the continual fluctuation in the sea-levels between the Malay Peninsula and the islands of Sumatra, Java and Borneo, which resulted in these lands being united and separated repeatedly during the Pleistocene, was a factor of outstanding importance as regards species formation in the Archipelago, and accounts for the very large number of groups of closely allied species existing in Malaysia to-day. Of less importance were the changes in sea-level between the Aru Islands, New Guinea and Australia on the Sahul Shelf during this period, although the effects were similar. The remaining large island groups were isolated throughout the periods under discussion.

The formation of a large number of the geographical races (subspecies) found in Malaysia and in the region of the Sahul Shelf to-day dates from the final elevation of the sea-level after the last low level of the Last Glaciation, whereby the then existing land-masses were separated finally into their constituent islands. While the present subspecies and species of the 'bird-wing' butterflies are approximately of Holocene and late Pleistocene origin respectively, the phylogenetic stages previous to these two belong to the late Tertiary. The author computes that the evolution of the Troides group as a whole has occupied a period of between three and twelve million years.

Two outstanding problems concerned with the distribution of the 'bird-wing' butterflies are the overlap of the two major groups in the Moluccas, and the curious discontinuous distribution of ancestral Ornithoptera, which occurred in the Moluccas and Solomons and was absent from New Guinea. It may be mentioned that one or two of the present-day species of *Euploea* Fabricius (Danaidæ) show a similar hiatus in distribution so far as New Guinea is concerned. Dr. Zeuner considers that both these anomalies are explicable on the theory of continental drift. If New Guinea has advanced to its present position from a more southerly one during the Tertiary and Pleistocene and pushed the Moluccas and Solomons apart, and the Moluccas have been moved round from a position whereby the northern Moluccas occupied a more easterly site than at present, then these distributional problems are resolved.

STUDIES OF POPULATION CHANGES

AMONG the papers read before the American Philosophical Society at its mid-winter meeting, February 19–20, 1943 (*Proc. Amer. Phil. Soc.*, 87, No. 2, August 16, 1943) is one by F. W. Notestein of the Office of Population Research, Princeton University, on "Some Implications of Population Change for Post-War Europe". Mr. Notestein points out that we have been living in a unique period of the world's demographic history—a period of unparalleled population growth, which in Western Europe is drawing to a close. After discussing the fundamentals of population change, he applies general principles based on the vital trends of the inter-war period to derive age schedules of fertility and mortality for the future, from which he and his colleagues have constructed a series of population projections for the years 1940–70 for the U.S.S.R. and each European nation as of the 1937 boundaries. The fundamental assumptions are: (1) that the future course of mortality and fertility will represent an orderly development of the trends of the post-war period; (2) that there will be no international migration; and (3) that there is no war.

These projections indicate that the north-western and central region will reach its maximum population by 1950; in England and Wales, Sweden, Estonia, France, Belgium and Switzerland the maximum will be attained or passed by 1945; in 1955 by Scotland, Latvia, Finland, Norway, Germany, Austria and Czechoslovakia. While the effect of the War cannot at present be estimated, assuming the losses in the present conflict are proportional in each age-group to those of the War of 1914–18, it can be computed that the German population of 1950 will be about 25 millions less because of the decline in fertility and 10 millions less because of the losses of two wars. Accordingly, Mr. Notestein suggests that throughout this region society must be re-oriented towards the interests of children, probably detracting somewhat from the current preoccupation with the needs of the aged. It may also have to be less oriented towards strictly individualistic values and more toward those of the group.

In southern and eastern Europe the principal characteristic of the period 1940–70 is a rapid increase in the persons of working age, and accordingly throughout the period there will be constant danger of pressure of population on developed resources in a region already suffering from pressure of population on its predominantly agricultural economy. Such pressures must be relieved in this region of deep hatreds if strife is to be avoided. Prompt relief, it is claimed, can only come from two sources: absorption of the region by the Soviet Union, which has ample resources and an enviable record in dealing with ethnic heterogeneity, or an economic and political solution by the Western Powers. The latter would be impossible if a series of small sovereign States were set up. The solution lies in the creation of a wide trade area of relatively free migration into which outside capital and skills are brought to foster industrialization and urbanization.

In contrast with the other regions, the Soviet Union faces rapid growth in all sections of its population more than five years of age, and this growth in population will probably be matched with a growth in power. The Soviet Union has ample natural resources to support its prospective population within its present boundaries, and Mr. Notestein concludes that it is difficult to escape the view that the Soviet Union in the coming decades will be the strongest single Power in the world. The United States, in his view, could not wisely stand apart from an association for collective security based on the mutual self-interest of the community of nations.

Included in this symposium of papers on post-war problems is a paper by the late Prof. Franz Boas of Columbia University, which was read before the Society on November 21, 1942. In this paper, "Individual, Family, Population and Race", are briefly summarized the results of an investigation of a number of highly mixed populations, like those of the eastern large cities of the United States, of other groups more uniform because members of a well-defined national group, and by contrast isolated groups that had for long intermarried among themselves, such as the Scandinavians of the Faroe Islands, the East Siberian tribes of the Chukchee Peninsula, Chippeway Indians of a few communities that have for long intermarried, the Bastards of South Africa, the Pitcairn islanders and a mixed Malay Dutch population from Kissar.

The results of the study demonstrate a sharp cleavage between the isolated groups and the two other groups, and Boas infers that there is no human group in existence which is so uniform either in fraternal groups or in family lines that any one individual can be considered as a representative of the group. In other words, there are no characteristics known that would allow us to claim that individual characteristics are determined by traits common to the whole group. The component individuals of any group vary markedly among themselves, and 'race' does not determine human behaviour. While Boas does not claim that it has been proved that biologically or genetically determined characteristics are exactly the same in all populations, he maintains that every known population, no matter on what principles it is selected, shows a wide degree of variation of forms; that no pure human race exists, and that behaviour is much more rigidly controlled by natural and social environment than by descent.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Saturday, January 1

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Prof. E. N. da C. Andrade, F.R.S.: "Vibrations and Waves", 3: "Sound Waves".*

Monday, January 3

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 2.30 p.m.—Mrs. Reginald Wyndham: "In the Netherlands Indies", with Kodachrome and other Films (Christmas Lecture for Young People).

SOCIETY OF CHEMICAL INDUSTRY (LONDON SECTION AND FOOD GROUP) (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 2.30 p.m.—Prof C. R. Harington, F.R.S.: "The Contribution of Chemistry to Immunology" (Jubilee Memorial Lecture).

Tuesday, January 4

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Prof. E. N. da C. Andrade, F.R.S.: "Vibrations and Waves", 4: "Visible Light".*

Tuesday, January 4—Wednesday, January 5

AGRICULTURAL EDUCATION ASSOCIATION (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London W.C.1).—Half-yearly Conference.

Tuesday, January 4

At 9.30 a.m. (Agriculture Section).—Dr. John Hammond: "The Breeding of Cattle for Milk or Meat"; Reports by Dr. S. Bartlett and Dr. J. Edwards on "The Reading and Cambridge Artificial Insemination Centres".

At 11 a.m. (Dairying Section).—Mr F. K. Neave: "The Sterilizing of Dairy Utensils by Hypochlorites"

At 11.15 a.m. (Chemistry Section).—Mr. W. Morley Davies: "Plant Nutrition".

At 2.30 p.m. (Paper Reading Session).—Discussion on "The Agricultural Education of the Youth of 15 years of Age and Over" (to be opened by Mr. A. S. McWilliam, Mr. C. R. E. Gillett and Mr. J. Hunter Smith).

Wednesday, January 5

At 9.30 a.m. (Paper Reading Session).—Mr. D J. McLaren. "Some Suggestions for Organizing Instruction in the Care, Maintenance and Use of Implements and Machinery within the County Agricultural Education Framework"; Mr. C. Davies: "Specialised Farm Machinery—What is Necessary and What is Customary".

Thursday, January 6

BRITISH ECOLOGICAL SOCIETY (in the Department of Botany, The University, Oxford), at 10 a.m.—Annual General Meeting.

ROYAL INSTITUTION (at 21 Albemarle Street, London, W 1), at 2.30 p m.—Prof. E. N. da C. Andrade, F.R S.: "Vibrations and Waves", 5: "Short Electromagnetic Waves".*

Friday, January 7

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 2.30 p.m.—Miss Francesca French: "China—the Western End of the Great Wall" (Christmas Lecture for Young People).

INSTITUTE OF PHYSICS (LONDON BRANCH) (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Dr. R. Stoneley, F.R.S.: "Earthquakes".

Saturday, January 8

GEOLOGISTS' ASSOCIATION (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Mr. C. E. N. Bromehead: "Geology and Health".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Prof. E. N. da C. Andrade, F.R S.: "Vibrations and Waves", 6: "Long Electromagnetic Waves".*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

HEADMASTER of the Ashington Mining School—The Director of Education, County Hall, Newcastle-upon-Tyne (January 7).

ASSISTANT (temporary) IN AGRICULTURE at the Somerset Farm Institute, Cannington, near Bridgwater—The Clerk to the Somerset County Council, County Hall, Taunton (January 10).

TIME AND MOTION STUDY ENGINEERS (Order No. Q.5662S), and TIME AND MOTION STUDY ASSISTANTS (Order No. Q.5663S), for Government Posts in the Provinces—The Ministry of Labour and National Service, Appointments Department, Sardinia Street, Kingsway, London, W.C.2 (quoting appropriate Order No.) (January 12).

TEACHER OF ENGINEERING SCIENCE, MATHEMATICS AND DRAWING in the Junior Technical School—Mr. E. B. Stockdale, Education Office, Mexborough, Yorkshire (January 14).

WOMAN PSYCHOLOGIST (whole time) at Twickenham Child Guidance Clinic—Mr. C. W. Ratcliffe, "R2", Clerk of the Middlesex County Council, Middlesex Guildhall, Westminster, London, S.W.1 (January 14).

TEACHER IN ENGINEERING SUBJECTS (possessing Graduate or equivalent qualifications in Mechanical Engineering and Industrial experience) at the Melton Mowbray and District County Technical College—The Director of Education, County Education Office, Grey Friars, Leicester (January 6).

GRADUATE (temporary) for MECHANICAL OR CIVIL ENGINEERING SUBJECTS, together with MATHEMATICS, at the Denbighshire Technical College, Wrexham—The Director of Education, Education Offices, Ruthin, Denbighshire (January 8).

Acting full-time DEMONSTRATOR OF ANATOMY—The Dean, Medical College, St. Bartholomew's Hospital, London, E.C.1 (January 11).

ENTOMOLOGIST in the Department of Agriculture, Salisbury, Southern Rhodesia—The Official Secretary, Office of the High Commissioner for Southern Rhodesia, 429 Strand, London, W.C.2 (January 31).

LECTURER ON PHYSICS—The School Secretary, St. Mary's Hospital Medical School, London, W.2 (February 1).

CHIEF ENGINEER for large Chemical Works near London, to take charge of Installation, Maintenance and Mechanical Running of Plant, together with the Upkeep of all Services—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No C.1869 XA).

LECTURER IN ENGINEERING in West Africa—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. E. 836A).

EDUCATION FOR THE VETERINARY PROFESSION

ON p. 60 of this issue we refer to some addresses which were given to the National Veterinary Medical Association of Great Britain and Ireland at its sixty-first annual general meeting in London last September. These addresses, and the discussions which followed them, make it clear that the veterinary profession is—and always must be—of fundamental importance to the health of man and to the progress of his civilization. In times like our own, when the basic importance of nutrition is being so often and so rightly emphasized by responsible authorities all over the world, it will scarcely be denied that without successful agriculture our post-war reconstruction will not succeed; and it will not be denied that the key to successful agriculture is a fertile soil. An important condition of soil fertility is the maintenance of a healthy livestock to fertilize it. Both the veterinary surgeon and the farmer are, therefore, key men of the future. They must always work in collaboration.

These fundamental conditions of successful agriculture have been recognized in recent years by the Ministry of Agriculture and by the Agricultural Research Council. Some years ago these bodies established a network of interacting links between the farmer and the veterinary surgeon on one hand and, on the other, between the farmer and experts in botany, soil science, genetics, farm economics, nutritional science and other branches of scientific inquiry which directly or indirectly affect the production by the farmer of the national food supply. These experts work either in agricultural institutes established and maintained by the Government, or in similar institutes which are attached, sometimes by the financial link only, to the universities. In these institutes or at other key points in Great Britain a number of advisory officers have been stationed by the Ministry of Agriculture, and it is the duty of these advisory officers to keep in touch with the farmers and to interpret to them the results of scientific research. Veterinary surgeons constitute one group of these advisory officers; and they, in the course of their work, bring not only the farmer but also the veterinary surgeon into relationship with the work of the universities. There is nothing in this scheme to bring the veterinary surgeon into relationship with the other great profession which deals with national health, namely, the medical profession; but there is no doubt that the scheme has greatly benefited the farmer and the veterinary surgeon and also the national production of food.

If, however, the farmer needs the veterinary surgeon to maintain his livestock for the purpose of fertilization of his soil and for crop-production, he needs him also to maintain the health and genetical constitution of a livestock which is in itself the raw material of our considerable industry in animals and their products. The value of this industry is estimated by the President of the National Veterinary Medical Association at some £200,000,000 a year. British livestock has, moreover, formed the nucleus

of the best herds and flocks of the Dominions overseas, of the Americas and of many other countries; because of the excellence of this stock, Great Britain has been called the stud farm of the world; and our trade in livestock exported for breeding purposes only has been a valuable one. Our breeding stock is, in the opinion of some experts, still in good condition, in spite of the difficulties of four years of war. Expert opinion, however, agrees with the Minister of Agriculture that this is not true of the general livestock in our fields. If this is so, it is not the fault of the veterinary profession, which works manfully against the difficulties of war to maintain the health of all our domesticated animals. The profession is not a large one. The President of the National Veterinary Medical Association (*Vet. Rec.*, **55**, 395; 1943) states that there are less than 3,000 active veterinary surgeons in Great Britain to-day, about one third of whom man the State Veterinary Service or hold other public, educational or similar whole-time appointments, the remainder being in private practice. They have by their constant vigilance so reduced the risk of the major rapidly spreading epidemics of disease in farm animals that it is negligible in Great Britain and in those of our Colonies where veterinary surgeons have been able to tackle diseases of this kind on their own responsibility. Losses from disease are nevertheless considerable in all countries. The President of the National Veterinary Medical Association estimates that they cost Great Britain £30,000,000 a year. To lessen this loss the veterinary profession is doing all that it can with the resources and facilities placed at its disposal. It has performed, and daily performs, many dull and exacting and unspectacular routine tasks of health supervision, meat inspection and the like. It is clear that its education and its general status is a matter of public importance. A brief review of its organization will help in understanding its position in relation to national affairs and the general trend of changes in this position which have either occurred recently or have been proposed for the future.

When John Hunter sponsored the foundation of the Royal Veterinary College of London, he began a process of education in animal health which will, if we read the signs of the times correctly, proceed to the position which responsible authorities desire, namely, the incorporation of veterinary education in a general scheme for the control of both animal and human health. Four other veterinary colleges now help the London College to undertake the education of veterinary surgeons. These are the Royal (Dick) Veterinary College of Edinburgh, the Glasgow Veterinary College (Incorporated), the Veterinary College of Ireland, Dublin, and the School of Veterinary Science of the University of Liverpool. The creation of two other colleges at Bristol and Cambridge has been recently suggested. All the existing colleges are authorized by Royal Sign Manual to train veterinary students for examinations which are held by one examining body and one only—the Royal College of Veterinary Surgeons. This is a corporate body established by Royal Charter in 1844 and composed of those who have been students of the affiliated colleges mentioned above and who have been admitted to membership of the Royal College by passing the examinations controlled by that College. The Royal College of Veterinary Surgeons is thus to be clearly distinguished from the Royal Veterinary College of London, which is purely a teaching college, and from the National Veterinary Medical Association, which is an association of qualified veterinary surgeons, and is akin to the British Medical Association. The functions of the Royal College of Veterinary Surgeons are analogous to those of the General Medical Council, except that the Council of the Royal College of Veterinary Surgeons has sole control of the only examinations which qualify a veterinary student to practise as a veterinary surgeon and of the examiners who conduct these examinations. Its further duties are to keep a register of veterinary surgeons and to discharge certain functions relating to the ethics of the profession and to the activities of unqualified individuals who attempt veterinary practice. Its functions thus amount to the maintenance of a high degree of professional efficiency and ethical conduct among its members. For some years the Council of the Royal College of Veterinary Surgeons has required the veterinary, like the medical, student to complete a training lasting five years; in this time he has to cover a field of work similar to, but wider in scope than, that covered by the medical man. When he has received the veterinary diploma (M.R.C.V.S.), the veterinary surgeon can, if he likes, take, under suitable conditions, such additional qualifications as the fellowship of the Royal College (F.R.C.V.S.) or the diploma in State veterinary medicine (D.V.S.M.), which are awarded by the Royal College alone, the diploma in tropical veterinary medicine (D.T.V.M.) awarded by the University of Edinburgh, or various postgraduate courses which are designed to give further instruction in pathology, bacteriology and public health, or to give special instruction to those who wish to enter the Royal Army Veterinary Corps or the Colonial Veterinary Services. Some universities also grant degrees in veterinary science, and the D.Sc. and Ph.D. are open to veterinary surgeons doing research in some universities. It is no new thing, either, for chemists, biologists and others to take advantage of the grants provided by the Ministry of Agriculture to become veterinarians as well.

In addition to these opportunities to advance his education and broaden his outlook, the modern veterinarian may look for aid to the funds and wise direction of the Veterinary Educational Trust. This trust, which was founded in 1942, was the subject of a leading article in these columns at that time (NATURE, **150**, 500; 1942). We then commended the aims of its founders, namely, the creation of an animal health organization, together with the provision of scholarships, fellowships and other aids which would do much to provide veterinarians with adequate education and opportunities to do their work; for the veterinarian is, we then insisted, one of the key men in our national affairs. *The Times*, *The Field*, the *Farmer's Weekly* and other far-seeing and well-informed authorities agreed with us then

that the new type of veterinarian who has come into the field must have the best possible training and mental equipment. Great Britain must no longer be reproached, as it is still being reproached, for its continued failure to accord to its veterinarians the status and educational facilities which are provided as a matter of course by other countries.

This brief outline of the existing veterinary education will, however, make it clear that events are moving slowly in the direction advocated in the leading article already referred to. Veterinary education is still too far divorced from the universities, but a nucleus of close collaboration with them exists; the existing system segregates the veterinary student and the qualified veterinarian from university workers, but it ensures a uniform standard in its examinations, and this is denied to the medical man and to some other professions. Whether this uniformity is worth the price paid for it in the dissociation, not only of veterinary students, but also of their teachers, from university life and work it is not our purpose to consider. It is pertinent, however, to direct attention to one aspect of this dissociation—its tendency to hinder the natural contacts between the work of the veterinary surgeon and that of the medical man.

Upon this point and upon the desirability of drawing together these two great professions by means of some educational scheme a great deal could be said by those veterinary surgeons and medical men who agree that it could do nothing but benefit both professions. No other professions are so closely connected as these. Both study the normal and deranged health of animals; both are concerned with the control of diseases which, like tuberculosis, trypanosomiasis, anthrax and others, are communicated to man from his domesticated animals; both are concerned with the production, in adequate quantity and quality and in freedom from disease, of basic foods such as eggs, milk and meat; both have made outstanding contributions to our knowledge of animal morphology, physiology and pathology and to bacteriology and the control of disease. Some men have, indeed, expressed their realization of the common aims of the two professions by acquiring the qualifications necessary to both; and the Royal Society of Medicine, when it established a section of comparative medicine, the proceedings of which are conducted jointly by medical men and veterinary surgeons, expressed its belief in the close co-operation of these two professions.

This co-operation, like the general collaboration between the veterinary surgeon and workers in other branches of scientific inquiry to which we have already referred, is, in fact, increasing in our chief centres of teaching and research. It is not, however, close enough. It ought to be an active, natural liaison. We say liaison because no one would propose that a closer association than this is possible. It would not be possible, even if it could be shown to be desirable, to educate the two professions in the same classes. The first year of their instruction can be so passed. In point of fact, in Edinburgh all students of Surgeons Hall and of the Dental College of Edinburgh are, at the request of their respective deans, doing their first-year physiology, histology and biochemistry at the Royal (Dick) Veterinary College during the War; but as soon as the student goes on to the study of anatomy and physiology, the special requirements and wider scope of the veterinary course make it necessary to give him special classes in the anatomy and physiology of the domesticated animals. He requires to know how to manage and care for these animals; and this is, in itself, a big undertaking, requiring the provision of a farm and a field station; it is, indeed, one of the major difficulties of veterinary education to-day. The veterinary student further requires, as his instruction proceeds, more and more instruction over and above that given to the medical student, who deals with one kind of animal only. No medical school could, for example, provide the clinical material which is essential for the teaching of the diagnosis and treatment, whether this be medical or surgical, of sick animals and for the teaching of veterinary obstetrics. The provision of this essential clinical material is, in fact, another major difficulty of modern veterinary education. It calls for the provision of veterinary hospitals at every veterinary teaching centre. It must be obvious that efficient veterinary education requires its own specially trained teachers and its own independent buildings. This need not mean, however, that an administrative scheme could not realize a close association between the students preparing to enter both the medical and the veterinary profession. It could with advantage require that medical and veterinary students should each utilize to the full the courses of instruction given to the other.

We thus reach the natural culmination of that educational process which began with the foundation of the veterinary teaching colleges. At the present moment the Loveday Committee is reconsidering on behalf of the Government the recommendations it made in 1938 for the improvement of veterinary education; at the same time the country is being told by the medical and lay Press something of the profound re-organization of the medical profession which is in progress. It is true that this medical re-organization appears on the surface to affect chiefly the practical treatment by the doctor of his patients, but it would be short-sighted to suppose that a revolution in practice of this order will not affect profoundly the education and, indeed, the whole outlook of the medical man. He is to become, it is clear, much more of a public servant and much less of an individual who practises, with whatever nobility of purpose, for his own private profit. It may be that a similar change will affect all of us, in one degree or another. The veterinary surgeon is already able to do public service by entering the Colonial veterinary services or the State veterinary service at home.

While changes so fundamental are being considered and planned in both the veterinary and the medical professions, it must surely be wise to consider also whether their education, at least, if not their practice, cannot be planned as a natural whole. Their basis

is the same, their principles are the same, so the end product of their education should be the same. Both professions should study to produce an alert, scientific, public-minded individual whose altruistic outlook moves him to choose as his life-work the science and art which seeks to relieve the sufferings of man and animals and to save their lives when they are attacked by disease. The best way of doing this is, as was pointed out in our leading article a year ago, to study to prevent the occurrence of disease rather than to try to cure it after it has occurred; and this is, in fact, the policy of both the veterinarian and the medical man of to-day. It would be difficult to find a better or a more powerful bond between them. In tune as it is with the whole trend of modern thought, it may well prove to be the only bond which is powerful enough to compose the differences which undoubtedly still exist between these two great professions.

SCIENCE AND RELIGION

Man, Real and Ideal

Observations and Reflections on Man's Nature, Development and Destiny. By Prof. Edwin Grant Conklin. Pp. xvii+247. (D.800.) (New York and London: C. Scribner's Sons, 1943.) 2.50 dollars.

PROF. CONKLIN'S book is well intentioned and well written, but, at least to me, profoundly unsatisfactory. The theme is, in the main, the time-honoured problem of the relation between science and religion, and it would be near the truth to say that, for the author, real man is man as science discloses him, while ideal man falls in the province of religion. Prof. Conklin evidently writes for a public which is still not unaffected by Fundamentalism, for echoes of the Tennessee controversy over evolution lend some of his remarks an asperity which English readers will consider strange. But the pages in which he outlines the evolution of man and the origin of races are clear and easy to understand by the general reader. They call for no comment except recognition of their admirable lucidity. He concludes that "the main direction of human progress has turned from the path of further differentiation of the individual to that of increasing differentiation and integration of society".

In spite of Prof. Conklin's exposition, I remain, as often, perplexed by the word 'evolution'. It seems to me that evolution is not a fact in the sense that it is a datum, but a theory to explain a large number of observed phenomena. What precisely the author's theory may be I find it impossible to say. He is certainly not a thoroughgoing Darwinian. Chance mutations and natural selection are not enough; there is an "unknown factor" in evolution, which appears to be more important than the known factors. All that the author will say about it is the somewhat vague question, "Is it unreasonable to suppose that something basic to intelligence and purpose is found in all organic evolution?" It will not surprise the reader who has made anything of this question that Prof. Conklin believes in a "non-personal" teleological tendency on which he builds rather more than the foundation will stand.

Behaviourism finds no favour with the author, who says, truly enough, that "to deny the reality of subjective phenomena is equivalent to denying the reality of all phenomena", and he inclines to the belief, or should we rather say hope, that divine immanence is the assumption which will maintain something like divine control or direction in evolution without conflicting with science. It is not, I think, unfair to say that when Prof. Conklin comes to deal with metaphysical problems his clearness of thought is obscured and we have the impression that he has not thought the meaning of his assertions through to the end. Thus he calls himself a "scientific realist" and he defines his attitude as follows: "I regard the external world as real and I think that objects are what they seem to be unless by scientific methods it can be shown that they are otherwise". The naïvety of this sentence disarms criticism, but it must be pointed out that almost every word in it raises epistemological problems of the most far-reaching character. We cannot stay on them, but it may at least be remarked that the further "scientific methods" are pushed the nearer we come to the position that *no* objects are "what they seem to be". Nor again can the assertion that idealist metaphysics "denies objective reality and therewith all science" be passed over without protest. The truth is that most idealist theories of the ultimate nature of reality leave science precisely where it was.

Perhaps it is useless to protest against the unscientific attitude adopted in this book to psychical research, because it is so common among scientific writers. Prof. Conklin believes that there is no scientific evidence in favour of personal survival of death, and states, no doubt accurately, that "the anecdotal evidence of psychical research leaves most scientists cold and unconvinced". This is merely an appeal to authority and not the result of an examination of the data, and surely no one who had followed the recent development of psychical research, for example, in the field of extra-sensory perception, could employ the epithet 'anecdotal'.

These are criticisms of detail, though I think of important detail, but it is not upon them that I base the opinion that the book is disappointing. Prof. Conklin has a real respect for religion and a keen perception of its place in human life. He writes eloquently of the pessimism of the 'pure realist' who allows no right to the religious experience. He is deeply concerned for the future of mankind and the preservation of ideal ends in life. He has a sincere reverence for the character and teaching of Jesus. No one could read what he has to say on these subjects without emotion and a feeling of affection for the author. But what does the religion which remains, when realism has done its work, amount to? I cannot see that it comes to anything more than the belief that possibly the hypothesis of God may be, in some undefined sense, true, that there are rather dubious signs of an immanent purpose in evolution, and that, if we all work very hard and keep our ideals bright, we may possibly produce a better world for our great-grandchildren. This will never do. If this is all that religion has of truth it will disappear. The root error of the book is the sharp distinction between reason and emotion and the relegation of religion to the emotional sphere. Religion has always claimed to be 'wisdom', to have an insight into the meaning of the world on which it stands or falls. The fundamental problem is never touched on in this book—the nature of scientific knowledge and its relation to other types of knowing.

Though I regard the book as, in its chief theme, superficial, I would not imply that it is not worth

reading, for it contains much incidental wisdom, mainly of a practical kind. I will conclude by quoting some sentences which express a truth needing to be emphasized. "It is time for some statesman or philosopher, some modern Plato, to draw up a Bill of Duties to match and balance our Bill of Rights. It is said that society owes every man a living, leisure, opportunity, freedom, but there is less emphasis upon what every man owes to society. There are no human rights that have not been earned by human effort, no social rights that are not balanced against social duties". W. R. MATTHEWS.

PROF. MOORE AND PHILOSOPHY

The Philosophy of G. E. Moore

Edited by Paul Arthur Schilpp. (The Library of Living Philosophers, Vol. 4.) Pp. xvi+717. (Evanston and Chicago: Northwestern University; London: Cambridge University Press, 1942.) 30s. net.

THIS book tries to reproduce the conditions of a seminar. There is a common theme: the philosophy of G. E. Moore; there are nineteen philosophers, considering, interpreting and criticizing Moore's presuppositions, approach and philosophic method—both in general and in the specific cases of ethics and the theory of perception; there is, finally, a lengthy answer by Prof. Moore in which he takes up some of the points raised and deals with them with particular relish for fine detail, avoiding, however, treatment of more general problems.

The nineteen essays seem quite independent of each other. None of the authors appears to have had the opportunity of taking account of the content of other contributions. I do not suggest that an agreement about views and a fusion of the exposition would have been desirable; but, if collaboration had been possible, some repetition of arguments in the five hundred pages of criticism might have been avoided and a more connected vision of Moore's philosophy achieved. The lack of collaboration is probably due to quite external circumstances, but the nature of Prof. Moore's reply cannot be thus accounted for. I cannot be alone in my poignant regret that G. E. Moore, after fifty years of philosophizing, embodied in reviews, essays, lectures and only one full-length book, did not give us—instead of a hundred and fifty pages of disconnected detail—a systematic account of his present philosophic position.

But I may be asking for the wrong thing. Perhaps it is not paradoxical to suggest in the face of this very voluminous book called "The Philosophy of G. E. Moore" that there is no such thing as the philosophy of G. E. Moore. There is indeed something: the attitude of G. E. Moore, and G. E. Moore's doubts, even bewilderment, about different philosophies. Something, I think, must here be said about this attitude. But I cannot hope to reproduce in a few words any of the important and penetrating things said by experts in this volume; nor dare I, without the opportunity for elaborate reasoning, contradict their points.

This book also contains an important weapon for the criticism of Moore's philosophic attitude, namely, his autobiography. This weapon, I suppose, has not been at the disposal of his nineteen critics. There is a method of philosophic criticism which is perhaps not universally recognized as fair and relevant; it is Nietzsche's 'unmasking'; that is, the tracing back of philosophic views to personal attitudes. If the autobiography—unlike the photographs included—is instrumental to the work's main purpose of philosophic elucidation, it can only suggest this method. If I seem to administer a kick from behind, I must insist that I have been specially led to take up this position. I quote an illuminating passage from the autobiography: "I do not think that the world or the sciences would ever have suggested to me any philosophic problems. What has suggested philosophic problems to me are things which other philosophers have said about the world or the sciences . . . first, the problem of trying to get really clear as to what on earth a given philosopher *meant* by something which he said, and, secondly, the problem of discovering what really satisfactory reasons there are for supposing that what he meant was true, or alternatively, was false".

I think that Moore's unwillingness to give an author the benefit of the doubt or to try to see—behind the inevitable misuse of language and the cramping effort of philosophic creation—that important insight and satisfactory vision flows from the attitude expressed in the quotation. It is from this point of view that he insists that he does not understand unless he is told in plain English. (Thus, for example, his surprising refusal to understand the word 'postulate' and therefore Mr. Edel's essay.) He is more interested in the minute inconsistencies of terminology than in the broad issues of which they are the vehicle.

Equally his defence of common sense flows from his preference for criticism to philosophic creation. While a defence of common sense may be a salutary corrective to some rash philosophic views, an imaginative conception of philosophy will not see in common sense an independent criterion, but only the popularized philosophy of the day before yesterday.

A different yet connected aspect of Moore's attitude is his position as reviver of 'realism'. I suggest that 'realism' as much as 'idealism' flows from, and is in an important sense largely an expression of, an experience of the way in which a mind works. This is certainly less than the last word about those philosophic schools, but perhaps more than an empirical statement of psychology. Moore's incapacity for, or mistrust of, creative speculation has led him to resign the claim of the mind-dependence of the world, just as Bradley's exuberance of creative force which speaks through his style and imagery tempted him into the elevation of mind to despotic power.

I have no space in which to make fully explicit the presuppositions of my approach. I have not undertaken to decide about the truth of philosophies or to pass value judgments upon them. It is perhaps obvious from my account that I believe much of Prof. Moore's approach futile. But it would be both useless and improper to assert a judgment without the opportunity for a full exposition of reasons. Only the utility of the whole work is here under consideration.

Moore's is a distinctive philosophic attitude which has exercised considerable influence. The critical consideration of this attitude and the ramifications symptomatic of its influence, together with his reply, certainly represents an important document about the state of philosophy in our time, and is rich in suggestions for the future critical historian of twentieth-century philosophy. H. P. REICHMANN.

PENICILLIN: ITS DEVELOPMENT FOR MEDICAL USES*

By PROF. H. W. FLOREY, F.R.S.
University of Oxford

PENICILLIN has received a great deal of publicity in the lay Press during the last year or two, largely, I suspect, because of the somewhat unusual and dramatic circumstances of its discovery and development. Though some of the accounts are substantially correct, others, both British and American, have not been so reliable.

It has been known since Pasteur described the phenomenon in 1877 that in a test tube in the laboratory, the growth of one species of bacterium may be stopped by the concomitant growth of another. It is now known that this is due to the production by the antagonistic micro-organism of a definite chemical product. To these naturally produced chemical inhibitors, the name of 'antibiotic' has recently been given. Pasteur recognized that the phenomenon of antibiosis might be of use in therapeutics, but the first serious attempt to use it was made by Emmerich and Loew in 1899, when they suggested that the products of a common micro-organism, *B. pyocyaneus*, could be used for treating anthrax and diphtheria. It is certainly true that this bacillus produces more than one antibiotic, but the mixture called 'pyocyanase' has never really been shown to be of use in medicine.

In the course of years, many examples of the production of antibiotics were found; in fact in 1929 a monograph was published about them, but none had at that time been employed successfully in medicine.

Discovery of Penicillin

In 1929, Prof. A. Fleming, of St. Mary's Hospital, London, made a very acute observation. He was examining the growth and properties of Staphylococcus. This organism grows readily on a solid medium containing agar. In the course of his observations, Fleming had to lift the lid on and off in order to examine the staphylococci growing in the dish. Now everywhere in the air around us are bacteria and spores of moulds. If the lid of an agar plate is left off for only a few minutes, bacteria and spores settle on the agar and in a few days the surface is covered with a thick growth of bacteria and moulds. During Fleming's short manipulations, a mould spore settled on his agar plate, which was then put aside for a few days. Such a contamination is extremely common, but what was remarkable in this instance was fortunately noticed by Fleming, who had for many years been interested in antiseptics. Around the mould colony, the colonies of staphylococci were undergoing lysis, that is, dissolving.

Fleming took some of the mould and cultivated it in flasks, in liquid broth. He found that during its growth something appeared in the broth which was capable of inhibiting the growth of a number of microbes, including many of those which cause some of the most destructive lesions the flesh is heir to. This substance Fleming called 'penicillin'. The mould was afterwards identified as *Penicillium notatum*. It is not a common mould, and is not the kind found on bread, old boots and such-like.

Fleming found that penicillin-containing broth was not more poisonous to animals than ordinary broth, and that the broth did not appear to harm white blood cells. He recognized that penicillin might be of value in medicine as an antiseptic to apply to infected wounds, and after treating a few indolent septic wounds with the broth, he concluded that, as he said, "it certainly appeared to be superior to dressings containing potent chemicals".

Clutterbuck, Lovell and Raistrick found in 1932 that the mould could be grown on a purely synthetic liquid medium, but they did not succeed in extracting the penicillin from the liquid in stable form. They found, however, that if the medium was acidified and shaken with ether, the penicillin passed into the ether. Unfortunately, when they tried to get rid of the ether and concentrate the penicillin by evaporation, most of the penicillin activity was lost.

Discovery of the Chemotherapeutic Effects of Penicillin

Fleming, and also Clutterbuck, Lovell and Raistrick, concluded that penicillin is a very unstable substance and therefore not likely to be a practicable antiseptic, and the matter rested there until the work was taken up at the School of Pathology, Oxford, in 1939. Since 1929, I had been interested in another discovery of Fleming's—lysozyme—a substance occurring in many animal tissues and secretions which has the power of dissolving certain air bacteria, though unfortunately none which produces disease. The work on lysozyme was continued on the biochemical side during the 1930's, until it was purified by Roberts in 1937, and the material or substrate on which it acted characterized by Epstein and Chain in 1940. During the latter part of this work in 1938, Dr. Chain and I decided that it would be profitable to make a systematic survey of naturally produced antibacterial substances both from a biochemical and biological aspect. The first two to be investigated were the products of *B. pyocyaneus*, the bacterium to which I have already referred, and penicillin. Penicillin was chosen (in spite of the fact that it was said to be very unstable) because it acted against disease-producing bacteria, in particular the staphylococcus. One observation of Fleming and of Clutterbuck, Lovell and Raistrick suggested that penicillin was not too unstable to handle; that was, that its activity might, under certain conditions, be maintained in the original medium for some weeks. At the beginning of the work we thought that penicillin would be an enzyme or ferment like lysozyme, and we were certainly unprepared to discover its remarkable properties which came to light in the course of the investigations. The work which we now began needed the close collaboration of many workers. In addition to Dr. E. Chain, these colleagues have been Dr. E. P. Abraham, Prof. A. D. Gardner, Dr. N. G. Heatley, Dr. M. A. Jennings, Dr. A. G. Sanders, Dr. C. M. Fletcher and Mrs. Florey, with the collab-

* Substance of a Friday discourse delivered at the Royal Institution on December 10.

oration of many surgeons and physicians; I should like to emphasize that without their unstinted efforts the work would never have been carried through to its present stage. Nor must one forget how much was due to our technical assistants, Mr. G. Glister and his 'penicillin girls', Mr. J. Kent and, for the chemical work, Mr. D. Callow.

One of the first steps was the elaboration by Heatley of a quick test for penicillin, which made the quick assay of penicillin-containing fluids possible.

At first the mould was grown in flasks; later, when more material was required, it was grown in larger vessels.

Preliminary experiments showed that penicillin was an acid which in the acid form rapidly lost its activity. It was also destroyed by alkali but was stable at a point which was neither acid nor alkaline, that is, about neutrality. Further, Clutterbuck, Lovell and Raistrick's observation was confirmed that, if penicillin-containing brew was made acid and shaken with ether, the penicillin passed into the ether. The crucial observation was then made that when the ether containing penicillin was shaken with water containing the right amount of alkali, the penicillin passed from the ether back into water. In this way the penicillin could be extracted from the crude brew and partially purified. The processes now used for the preparation of penicillin all depend, at one stage or another, on transference of penicillin from a water solution to an organic solvent and back.

It must be realized that in the early days we had very little penicillin for the experimental work on which some of the essential chemical data were obtained. The main factors affecting the use of penicillin in medicine are that salts of penicillin: (1) are stable about neutrality; (2) they are destroyed by acid and alkalis; (3) by oxidizing agents such as potassium permanganate; (4) by certain metals such as copper, lead and mercury; (5) by some alcohols; and (6) by enzymes or ferments produced by certain air bacteria.

One of the most important points is its destruction by an enzyme or ferment produced by certain air bacteria. These bacteria are ubiquitous and very easily contaminate the fluids in which penicillin is grown. If this occurs, the enzyme produced by the bacteria destroy the penicillin as fast as the mould produces it. It is, in fact, the air bacteria which make large-scale production of penicillin so difficult, for it is by no means easy to carry out manipulations on a large scale while excluding these organisms.

The isolation from the original medium of a protein- and salt-free product made possible a study of the bacteriological and pharmacological properties in detail.

Some of the bacteria highly susceptible to penicillin are *Streptococcus pyogenes* (causing pus formation and such diseases as child-bed fever), *Staphylococcus aureus* (causing bone diseases and boils, etc.), both of which are important in war wounds, *Streptococcus pneumoniæ* (causing pneumonia), *Corynebacterium diphtheriæ* (causing diphtheria), *Clostridium welchii, septique* and *œdematiens* (causing gas gangrene), *Neisseria gonorrhœæ* (causing gonorrhœa), *Neisseria meningitidis* (causing meningitis or spotted fever).

Some much less sensitive are those causing typhoid fever and a form of food poisoning, while some, such as those causing plague, cholera, dysentery and tuberculosis, are quite insensitive. It is thus clear that penicillin is not a cure-all, and it cannot be expected to act except in diseases caused by susceptible organisms.

Most antiseptics, like carbolic acid, kill the germs outright; but penicillin merely stops their growth, that is, it is what is called a bacteriostatic. It interferes in some way not yet clear with bacterial division.

Some of the first material produced inhibited the growth of an organism such as the streptococcus at a dilution of 1 : 1,000,000. We made the erroneous deduction that anything so powerful as this must be fairly pure, but we now know that only about 1 to 2 per cent of the original brown powder was pure penicillin. What is now commonly called penicillin for use in medicine still contains not more than 10–20 per cent of the active material, the rest being coloured and other impurities.

Pharmacological Properties

While this chemical and bacteriological work was proceeding, investigations were also made on its pharmacological properties. The most important points are: (1) lack of toxicity to mice and other animals; (2) white blood cells (leucocytes) and tissue cultures (body cells grown in glass vessels) are unaffected by concentrations of penicillin some hundred of times greater than that necessary to stop bacterial growth; (3) the activity of penicillin is not affected by pus, blood or the breakdown products of dead tissues; (4) its activity is little affected by the number of bacteria present; (5) it is absorbed after injection into muscle or beneath the skin and from the small intestine; (6) it cannot be given by stomach owing to the presence of acid there, nor by the large bowel owing to the presence of bacteria which destroy it; (7) it is very rapidly excreted by the urine, hence large and frequent doses have to be given. It is also excreted in the bile.

Points 3 and 4 are in sharp contrast to the sulphonamides.

It is most important that penicillin has little effect on the white blood cells or leucocytes, for it is to these that we owe a great deal of the capacity of the body to combat infection. If germs gain entrance, say, through a prick in the finger, the blood vessels dilate and certain of the white blood cells emigrate from the blood vessels to the tissues. They move freely about in the tissues, where they take up and kill bacteria if they meet them. But the bacteria produce poisons which kill the white blood cells, and the outcome of the infection is to a large extent controlled by which factor is the greater—the killing of the leucocytes by the bacteria or vice versa.

It will now be appreciated how penicillin acts in combating bacteria which have gained entry to the body. It stops the growth of the germs, while the white blood cells ingest them and kill them off.

The final experiments which demonstrated that penicillin might be useful in medicine were those known as mouse protection experiments. A number of mice are inoculated with germs which will certainly kill them if no successful treatment is given. We sat up through the night injecting penicillin every three hours into the treated group, and I must confess that it was one of the more exciting moments when we found in the morning that all the untreated mice were dead and all the penicillin-treated ones alive. The diseases treated experimentally were

caused by the streptococcus, the staphylococcus and a gas gangrene organism. Against the latter two organisms there is no other really effective drug.

A man is roughly 3,000 times the weight of a mouse, so you can well imagine that the next step, to produce enough to use on man, took months of labour on the scale at which we were then working. Eventually enough was made to give a single small injection to a man. Much to our consternation, the patient started shivering and the temperature rose. Fortunately, the substance causing this reaction was not penicillin, and the impurity was removed quite easily by chemical means.

Work in the laboratory having provided all the necessary knowledge to enable us to say penicillin could be used on man, and what sort of infections it was likely to deal with, the object of the first trials on man was to see if the drug exhibited any toxicity not found in animals and to ascertain the best methods of administration and the necessary dosage.

Penicillin can be used in two ways; it can be injected intravenously or intramuscularly, after which it is carried by the blood stream to the diseased parts. By this means much penicillin has to be used, but it is the only possible way of giving it in many serious illnesses. It may also be used in much less quantities as a local application to infected parts. Its successful use locally clearly depends on being able to reach every part of the diseased area, and one of the main points in its use is the elaboration of the requisite surgical techniques to ensure this.

There is no question that this drug can perform in a remarkable way when rightly used but, as with all new drugs, the initial trials tend to be carried out on what are considered hopeless cases after everything else has been tried. Though it is recognized now that penicillin is a valuable drug, it is still so rare that patients are not treated until the disease has progressed a long way and everything else has been tried. What one looks forward to is its use at the earliest possible moment with the idea of stopping or preventing destruction of the tissues, and so saving much disability and prolonged illness, and even life. It is probably along these lines of prevention, for example, that it will be most profitable to use the material for those wounded in battle.

At the present time there are dozens of chemists both in Great Britain and in the United States, in academic laboratories and commercial firms, engaged on the chemical problems, and we must await the result of their labours with what patience we can. In the meantime, great efforts are being made to improve the yields produced by the mould by means of selecting a good specimen or strain of the mould, and by improving the media. A considerable measure of success has been achieved, particularly by our American colleagues. Just as the Americans have had our information we have theirs, and commercial firms both in Great Britain and America are now doing all they can to make this drug available in quantity in the shortest possible time.

I venture to suggest that in another five or ten years the work I have been describing will be looked on as the first halting steps in the exploration of a whole series of new chemotherapeutic compounds, and I think the discovery and development of penicillin may be looked on as quite one of the luckiest accidents that have occurred in medicine, for without exception all other mould antibiotics so far examined are poisonous.

INFLUENCE OF NEWTON'S WORK ON SCIENTIFIC THOUGHT*

By N. TEICH,
University of Leeds

BY his extraordinary talent Newton was able not only to produce a powerful synthesis of the work done by his immediate predecessors, Galileo and Kepler, but also to add profound contributions of his own to mechanics, mathematics and optics. His method of fluxions enabled him to produce quantitative calculations which raised the level of mechanical science to hitherto unknown heights. The mechanical interpretation of Nature to which he gave such a powerful stimulus became one of the leading factors in the subsequent development of scientific thought.

The question arises now whether it is possible in discussing the scientific side of Newton's influence to omit his influence on the philosophical and social side? Evolution of scientific thought does not depend only on experiments and calculations. It is true that scientific men are in the first place responsible for scientific thought. But they do not live in a vacuum. They are social beings; they take part consciously or unconsciously in the life of society surrounding them. Social ideas which agitate society also affect their ideas.

What was the social background to which we have to look in order to understand the essential levers of Newton's work? Whoever takes a plunge into the history of Newton's period cannot help observing that the intellectual activities of Newton and his contemporaries went side by side with the struggle for political rights between the old nobility and the rising class of merchants. All activities in military and commercial spheres needed the active help of people well versed in the theoretical principles of astronomy (for navigation) and of mechanics (for building simple machines or using cannons). It is not surprising, therefore, that the physical theory of that time occupied itself mainly with the motions of stars or of bodies encountered in everyday experience. People needed scientific knowledge in order to improve their living. What Francis Bacon hoped for when he said that "the roads of human power and human knowledge lie close together" became a reality more than ever before at the time of Newton in England, and at the end of the eighteenth century in France. It is no accident that the essentially materialistic conception of mechanical science scored such a profound victory first in England, then in France, because in these countries the social changes which we associate with the bourgeois revolutions of 1642 and 1789 were favourable to a materialistic philosophy.

Although the immediate social impacts gave rise to the comprehensive theory and practice of mechanics as worked out by Newton, we must not forget the historical continuity which binds the Newtonian outlook to the earlier English materialists, Roger Bacon and Francis Bacon, and to the schoolmen Duns Scotus and William of Occam. English materialistic thought culminated in Newton's work in mechanical science despite the theological limitation Newton imposed on himself.

The brilliant success of Newton's work as applied

* Essay awarded the Foyle Prize of the University of Leeds.

to practical problems of everyday life accounts for the widespread use of mechanical interpretation in nearly every field of human knowledge. Thus David Hartley, the social investigator, in order to justify his own method of approach said: "The proper method of philosophizing seems to be, to discover and establish the general laws of action affecting the subject under consideration under certain select, well defined and well attested phenomena, and then to explain, and predict the other phenomena by these laws. This is the method of analysis and synthesis recommended and followed by Sir Isaac Newton."

At this juncture it might, perhaps, not be out of place to turn to the relation of philosophy to science. Broadly speaking, philosophy at every stage of its development has reflected on Nature, and by proposing a comprehensive view of it has pretended to know it. Although philosophy has often abandoned reality—and thus Nature, the object of its study—we have to give it credit, at any rate, for posing the question of evolution earlier than natural science. Thus the great German philosopher Kant tackled the origin and constitution of the solar system forty years before Laplace. Natural science arose just because official philosophy came increasingly into conflict with everyday experience. Afterwards it became apparent that natural science was taking over one domain after another considered to be under the jurisdiction of philosophy. This development reflected itself in the division of science into physics, chemistry, biology and other branches. This division, of course, was inevitable in view of the complex processes which characterize natural phenomena. Precisely because of this complexity, scientific men were initially unable to see processes in Nature but only phenomena in isolation. In this light we have to see the development of mechanics as a well-defined science, the subject of which was particles in isolation connected only by forces. By the mid-nineteenth century enough was known of natural phenomena to show that they constituted continuously changing processes. Knowledge of these processes through natural science alone was able to give a relatively full picture of Nature. A special knowledge through philosophy could be dispensed with. However, Kant's 'thing-in-itself' lay equally heavy on philosophers and men of science. Thus actually science and philosophy continued to exist side by side, sometimes in mutual opposition, sometimes in mutual support, of each other's theories.

The request for the support of science is a sign of progressive thought. In eighteenth-century France, the absolute monarchy was being undermined by the demands of the middle classes for political rights. Great and daring writers reflected in their publications the approaching storm of the Great Revolution. For our purpose it is important to note that these writers philosophically reared by Descartes based their arguments on science, which meant the mechanical science brought to the highest pitch of perfection by Sir Isaac Newton. The precision by which his theoretical calculations were proved when applied to everyday practice created an atmosphere of confidence as much in scientific as among political circles.

Descartes postulated mechanical science as the focal point of the interpretation of Nature, and Newton demonstrated by actual calculations and experiments the truth of this new scientific thought. Descartes came to the conclusion that mind and matter were separate; Newton through his unrivalled authority in the fields of mathematics and mechanics gave it a form of Papal blessing, showing that the world was able to live on its own, having been given the famous external impulse by a being whom Newton identified with God. The ripest fruit of this Cartesian-Newtonian interaction is perhaps LaMettrie's work "Man the Machine".

The social ferment in France gave rise to a thirst for knowledge. We witness a spread of scientific education, primarily concentrated in artillery schools. Laplace and Lagrange, perhaps the most brilliant Newtonians, were pupils in these schools. Laplace, though as a whole following Newton, was the first to apply mathematics to the problem of the origin of the solar system, which Newton probably considered to be outside scientific investigation. But even his authority could not prevent searching minds thinking about it, because it was realized, if only vaguely, that since everything around changed and developed, there must be some rational origin of the solar system. Incidentally, the Kant-Laplace nebular hypothesis was to be a stepping-stone for geologists to start work on the origin of the earth.

In his attempt to explain natural phenomena Lagrange followed a similar line in his "Mécanique analitique" published in 1787. Newton's "Principia" was published exactly a hundred years earlier. Whitehead points out that these hundred years contained the first period of mathematical physics of the modern type, and that the publication of Clerk Maxwell's "Electricity and Magnetism" in 1873 marked the close of the second period. He thinks that "each of these three books introduces new horizons of thought affecting everything which comes after them".

Though highly mathematical and abstract, these books express the technical and practical problems of the day. Thus it is often said that Clerk Maxwell translated Faraday's work into mathematical language; and Faraday's work was mainly connected with electrochemistry and electromagnetic induction, both of primary importance in industrial practice. It is not without reason that the authors of the above-mentioned books were in the order: Englishman, Frenchman, Englishman. The order reflects the comparative historic importance of their respective countries in the political and economic development of Europe.

With Clerk Maxwell we find ourselves in the nineteenth century. What was the social background of England at that time? Previously, small-scale enterprise developed into factories. England became the workshop of the world. Great problems of power supply and its measurement arose. Such is the social framework into which we have to fit Faraday's work on transformation of mechanical energy into electrical, or Joule's measurements of the mechanical equivalent of heat. A tremendous drive in industrialization was largely possible, because the preliminary scientific discoveries based on the work of Newton and his immediate successors were available. But the industrial revolution begot new scientific problems of its own. For our purpose it is important to note that the scientific men of this time were gradually ceasing to preoccupy themselves with particles and matter, and shifted their interests to fields and energies. We have seen already that Newtonian rigid mechanical assumptions were not accepted unconditionally. Hence the emergence of the Kant-

Laplace theory. In this century physical thought departed more and more from the Newtonian mechanical view. Physicists, in order to describe reality in a profounder fashion, were turning their eyes to the environment of the particles—to the fields which they considered to be stores of energy.

Initially, at this stage, physicists, moulded in Newtonian mechanics, explained energetic phenomena mechanically. The great German scientist Helmholtz expressed it in these words: "The final goal of all natural science is to develop into mechanics". Thus heat energy was recognized to be the outcome of the motion of molecules of matter. Maxwell's mathematical equations provided an all-embracing theory of optics and electromagnetism. Still influenced by the mechanical interpretation of Nature, men of science tried to find a material medium for the propagation of electromagnetic waves. Rapidly advancing scientific technology gave birth to fine instruments which showed a discrepancy between theory and experiment. The medium for wave motion—ether—endowed with many directly opposite qualities, had to be abandoned after the Morley-Michelson experiment failed to prove its existence. The mechanical view receded gradually into the background of the study of dead matter, whereas in biology it was rather unsuccessfully sustained, mainly by the Germans Vogt and Büchner.

From closer study of the history of science it can be seen that scientific advance is not a smooth progress, but takes a somewhat zigzag path. It is continuous and discontinuous at the same time. At any time scientific ideas embody in themselves many older, together with newer, views. Newton's influence in this period was of such a nature. He had been disproved in the question of corpuscular theory of light by Young and Fresnel, he had been looked upon sceptically by those to whom a mechanical method of interpretation of Nature seemed to be incorrect. On the other hand, his general concept of absolute space and time was unchallenged and tacitly assumed. The main function of his space seemed to be to transmit waves of electromagnetic nature of various frequencies, that is, to transmit energy essentially devoid of matter.

In the eighteenth century scientific men believed with Newton that the world was filled with particles, some ponderable, some imponderable. This mechanical view was opposed by the nineteenth-century physicists when applied to the corpuscular theory of light, on account of its inability to explain satisfactorily the interference of light. The corpuscular theory and the wave theory had competed for the favour of physicists since the time of Newton and Huygens and seemed to be irreconcilable. Suddenly, in the early part of the twentieth century, it was discovered that light may possess both properties. As Einstein and Infeld write: "No one thought of applying this concept [that is, the concept of energy] to the corpuscular theory of light. Newton's theory was dead and until our own century its revival was not taken seriously."

The reconciliation was the outcome of a suggestion put forward by Planck to explain certain experimental results in radiation problems. Introducing the elementary quantum of energy, he proposed the atomization of energy. The scientific world was faced with the dilemma of regarding energy as discontinuous after having for a long time considered it to be continuous. Einstein elaborated Planck's suggestion with respect to light energy, when he revived Newton's light corpuscles in his shower of photons or quanta of light energy. If Einstein, on one hand, brought Newton to the fore again, on the other he became aware of the limitations of Newtonian hypotheses. The contradictions in the Newtonian system evolved gradually, aided by the new scientific technique. Thus Einstein and Infeld write: "The theory of relativity arises from the field problems. The contradictions and inconsistencies of the old theory forced us to ascribe new properties to the time-space continuum, to the scene of all events in our physical world." Einstein, in proposing this revolutionary theory, utilized the great advances in physical theory and practice made since Newton. As the field theories are connected with Newton's mechanics, so the relativity theory is connected with field problems. In both cases this close connexion does not preclude the emergence of an essentially new picture of the working of natural phenomena. Thus the new phase of physics includes Newton's physics as part of a more general and richer physical theory corresponding to the new experimental facts.

The formulation of the law of conservation of mass is perhaps the most general reflexion of the mechanical thought which permeated the eighteenth century, when scientific workers were influenced by the thought expressed by Newton: "I am induced by many reasons to suspect that all the phenomena of nature may depend upon certain forces by which particles of bodies by some causes hitherto unknown are either naturally impelled towards each other and cohere in regular figures, or are repelled and recede from each other".

The formulation of the law of conservation of energy reflects, on the other hand, the change in the physical thought of the nineteenth century. Matter and mass were relegated to a secondary position by field and energy. Though the concept of energy helped to advance physics, the physicists were not at all sure what it really was. Whitehead, describing this state of affairs, says that "energy depends on the notion of an organism. The question is, can we define an organism without recurrence to the concept of matter . . . ?"

In the twentieth century, as a direct outcome of the relativity theory, mass and energy are found to be interconvertible. The two above-mentioned laws are combined into one conservation law of mass-energy; and the equivalence foreshadows the wave-particle equivalence in the electron. This contradiction in physics, that we have apparently two opposite concepts describing one of the fundamental units of the material world, can be understood as a contradiction between content and form. The particle side of the electron forms its material content, which has a wave-like form. This contradiction is dynamic and expresses itself in their interconversion. The same on a somewhat higher plane applies to the mass-energy interconversion. Modern physics has arrived at a point where Newton's postulate describing natural phenomena in terms of particles is still fulfilled: yet there is a great difference. Newton and his mechanical school could not explain qualitative changes. To-day we know that physical theory has to take account of the fact that, when things are summed, the process is not only quantitative, but also involves a qualitative change as well. A glance at the table of chemical elements will soon convince us.

Since mathematics proved to be a first-class tool by which natural phenomena can be understood, it is obvious that with the growing complexity of these phenomena the mathematical side is becoming more and more complex, hence more abstract, while through this quantitative treatment our knowledge of Nature is really becoming more and more concrete. This contradiction links up with yet another contradiction which exists between science and social organization. It is a paradox that while the scientific worker is more than anybody else responsible for the great advances of civilization, he is at the same time to a great extent divorced from the realities of everyday life.

This contradictory state in science and society forms the background to the efforts of powerful anti-social circles who would encourage the perversion of science into an instrument of destruction. There are scientific men who, perhaps genuinely trying to build for themselves a philosophical framework within which they can work, support these efforts unconsciously. Their books form a useful ally for those who have no interest in science as a progressive factor of social life. As Sir Charles Darwin says: "They excite the wonder of the reader by suggesting to him what extraordinary difficulties there are in the ideas of physics; they are like a conjurer whose tricks seem to us inexplicable". There are others, happily not a majority, who support such moves wholeheartedly. We have only to quote the Nazi leader Rosenberg about one of these men of science to illustrate the point: "As a thinker Professor Lenard has taught all knowledge is not the same, but souls of alien races produce bodies of knowledge of different spiritual contents".

It is in connexion with these terrible distortions of science that we have to study Newton and his influence on scientific thought, so that this study is not solely of an academic nature. Newton's principles are perhaps best described by Randall, when he says that his most significant contribution lay in the fact that he proved that the ordinary physical laws which hold good on the surface of the earth are valid throughout the solar system. This positive content of Newton's teaching, his objectivism and rationalism, has been transmitted to us by Laplace and Lagrange, by Lavoisier and Dalton, by Planck and Einstein, and in fact has become one of the main features of general scientific thought. The gulf between Lenard and Newton is obvious.

It is in connexion with this gulf that we have to study Newton and his period. There the interdependence of science with the outside world is fairly straightforward. Science and productive forces were in their infancy and their mutual relationship comes out clearly. We can see from it that science has social roots, that the character of scientific progress depends upon social changes. If the main social forces at a definite period are such that men are conscious of their tasks and are striving to solve them, then science progresses too.

What is the task which faces the man of science in this struggle? The answer given by Bernal is: "The task which the scientists have undertaken—the understanding and control of Nature and of man himself—is merely the conscious expression of the task of human society." If we agree with him then we recognize in Newton a great fighter for this aim, and his rationalism and objectivism an essential weapon through the ages which it is our duty to guard.

THEORIES OF TRICHROMATIC VISION

By PROF. H. HARTRIDGE, F.R.S.

THERE are frequent discussions concerning the rival hypotheses of colour vision, but seldom, if ever, do we see discussed the relative positions of the two rival theories of trichromatic vision. There are two possible plans which present different advantages. These are: (1) That each cone of the retina is able to respond to every one of the three kinds of sensation, red, green and blue; (2) that there are three entirely different kinds of cone, one for the sensation of red, one for the sensation of green, and one for the sensation of blue. The advantages and disadvantages of these two rival hypotheses will now be considered in turn.

The Single-Cone Hypothesis

According to this hypothesis, every cone of the retina is capable of responding to more than one colour sensation. In the fovea centralis every cone can give responses to three colour sensations. In the more peripheral parts of the retina, however, the responses of the cones may be somewhat curtailed to account for the diminution of the colour sense which is found there experimentally.

So far as is known, no single nerve fibre is capable of transmitting more than one kind of nerve impulse. Moreover, each cone of the retina connects with one fibre of the optic nerve and no more. In consequence, every cone must be capable of transmitting up its nerve fibre three different sensations, and this can only be done by variations either in frequency or in the pattern of the nerve impulses which are sent up to the brain. Suppose, for example, that when a cone responds to red rays it sends up its nerve fibre 100 impulses per second, whereas when responding to green it sends up 300 and for blue 1,000. Then, provided that the brain has the necessary structure for recognizing these three different frequencies, recognition of red, green or blue may be satisfactorily explained. When, however, two colour sensations are simultaneously being perceived, there would have to be a transmission of two separate frequencies to the brain. It does not seem easy to picture the simultaneous transmission of two such frequencies. But, on the other hand, alternative bursts of the two frequencies is not improbable; for example, suppose a cone were to be responding to red and green stimuli simultaneously, then a short burst of 100 nerve impulses per second would be followed by a short burst of 300 nerve impulses per second, and so on in alternation so long as the stimulus lasted. When white light is falling on the retina and, in consequence, according to the trichromatic theory, all three sensations are being aroused, there would have to be alternations of the three frequencies, each lasting for

a short period, and being followed in turn by the remainder.

Now since the type of colour sensation is determined by frequency, it is impossible for intensity of light to be transmitted by any variation in the number of nerve impulses per second sent up the particular nerve fibre. In consequence, it is a corollary of this hypothesis that each cone performs in an all-or-none manner, and that different cones have different thresholds, so that as the intensity of light increases the number of cones responding to that light increases; thus the active cone population will be small when light intensity is small and will increase to a maximum number as light intensity increases. Sooner or later, as this increase in light intensity continues, the whole of the cone population will have been brought into a state of activity, and further increase of light intensity which takes place will not cause a corresponding increase in the intensity of the sensation received by the brain.

The advantages and disadvantages of this theory may be stated as follows.

Since each cone responds to every colour, visual acuity with coloured light should be exactly equal to visual acuity with white light, and this fits in with experimental observation, any variations which are met with in practice being accounted for without difficulty, by variations in the sharpness of the image projected on the retina by the optical system of the eye. Since the number of active cones increases with the increase of light intensity, an explanation is given for the increase in visual acuity which is observed as light intensity increases. This theory also gives a reasonable explanation of the appreciation of variation of light intensity, since the small increase of light intensity is accompanied by an increase in the number of active cones. This theory gives no explanation of the important observations of Styles and Crawford, who found that the directional effect of the retina differed considerably in detail according as red rays, green rays or blue rays were used for the investigation. It would have been expected, on this theory, that the directional effect would have been the same for all colours, since the colours make use of identically the same cones.

The Triple-Cone Hypothesis

According to this hypothesis, every cone of the retina is capable of responding to one colour sensation only. Thus, in the fovea centralis, there must be three different types of cone, those responding to red, those to green, and those to blue. In the more peripheral parts of the retina, however, one of these types of cone, namely the green, may be reduced in number or may be omitted altogether in order to account for the diminution of the colour sense which is found there experimentally.

According to this hypothesis, the brain receives nerve impulses which inform it of the colours present in the image formed on the retina. It is possible that every one of these cones behaves in an all-or-none manner as was suggested by Hecht, but it is also possible that each of these cones responds in a graded manner, sending impulses along the optic nerves which vary in frequency according to the intensity of light which is falling on the cone in question. This view, which was suggested by me, has been supported experimentally by Hartline and others. This theory fits in admirably with the directional effects found by Styles and Crawford, namely that red light, green light and blue light each has a directional effect which differs from that of the others.

An apparent difficulty is met with in connexion with visual acuity which, at first sight, should have a markedly lower value for light of a single colour than is found for white light, since only about one third the number of cones is being stimulated. This difficulty is, however, avoided when it is remembered that in any random distribution of several different populations there are always places to be found where one population predominates over the others. An excellent example of this is the colour screen of the Lumière photographic plate. In this, there are distributed irregularly three different coloured groups of starch grains, red grains, green grains and blue grains. When such a screen is looked at with the naked eye, red, green and blue dots are clearly visible. On examining these dots with a microscope it is seen that they are not due to isolated starch grains but to quite large groups of grains of almost entirely one colour. Now if the cones of different colour response are distributed irregularly in the same way, then we should expect to find places where red cones predominate and other places where green cones are in excess, and other places again where blue cones are nearly exclusively present. In consequence, when high visual acuity is wanted for any one colour, it is possible to obtain it by causing the image of the object in question to fall on a part of the retina where the cones sensitive to that colour predominate. In the case of yellow light, a spot where there is a predominance of both red and green cones with the almost complete exclusion of blue cones would be most suitable for the purpose.

Evidence of Colour-Blindness

As is well known, colour-blind persons usually fall into one of four categories: (1) protonopes, who are red blind; (2) deuteronopes, who are green blind; and (3) tritonopes, who are blue blind; and (4) anomalous trichromats, who have abnormal colour vision which is, however, less severe than that of any of the three classes mentioned above. The first three types are readily explained on the triple cone hypothesis by supposing that the cone responsible for the missing sensation is either entirely absent or is defective, whereas anomalous vision is explained by a partial defect in one of the sets of cones, usually the green. In the case of the single-cone hypothesis, an explanation has to be sought for on the following lines: either there is deficient in the retina a chemical substance capable of absorbing light of the missing colour, or that the cones themselves are unable to respond to the catalytic products of this chemical substance when it has been broken down by the action of light. Of these two alternative explanations, the first seems to be the more plausible and the easier to picture, although it should be pointed out that there is no histological evidence for the deficiency of one particular type of cone in the retinas of colour-blind persons. In consequence, colour-blindness, which might have been expected to differentiate between these two theories and to eliminate one of them, in actual fact fails to do so.

Conclusions

We have seen that there are two rival mechanisms, both of which will provide trichromatic vision. Of these, the one which most closely fits in with the known facts is that which postulates three different varieties of cone, one corresponding to red light, another to green light, and a third to blue light.

OBITUARIES

Mr. James MacLehose, LL.D.

JAMES MACLEHOSE, chairman and managing director of Robert MacLehose and Co., Ltd., printers to the University of Glasgow, died at his home, 5 Heriot Row, Edinburgh, on December 14, 1943. He was born at Glasgow on April 9, 1857, the second son of that James MacLehose, publisher and bookseller to the University of Glasgow, whose name figures frequently in Mr. Charles Morgan's charming book, "The House of Macmillan".

James MacLehose was educated at the University of Glasgow, to which he proved a loyal son, and with which he was intimately associated both as bookseller and publisher for many years, and as printer for a longer period. From 1899 until 1909 he was vice-president of the board of management of the Students' Union. His services to scholarship fall under four heads: his eminence as a printer, his work as an author, his editorship, throughout twenty-five fruitful years, of the *Scottish Historical Review*, and his value as an active member of the board of trustees of the National Library of Scotland, the Advisory Committee on Scottish Records, the Scottish History Society and similar bodies.

He has himself stated that his "firm has endeavoured, not without some measure of success, to take its share in upholding the reputation of Scottish and also of British printing". This modest claim was fully substantiated by the elegance and accuracy of the work produced. He maintained the Foulis tradition in Glasgow. He was proud of the edition of "Hakluyt's Voyages" in twelve volumes, and of "Purchas his Pilgrimes" in twenty volumes, produced almost forty years ago, and, in recent years, of the great edition of Scott's Letters edited by Sir Herbert Grierson and published by Constable and Co. His press was identified with the production of volumes on higher mathematics and with the "development of colour printing and its use in educational and medical books". Its imprint has appeared on innumerable school and university text-books. Furthermore, he was the historian of his craft. His volume, "The Glasgow University Press, 1638–1931", was marked by painstaking research and an unflinching desire to arrive at the truth.

These qualities had been sharpened and burnished by his editorship of the *Scottish Historical Review* (October 1903–July 1928), his greatest contribution to the intellectual life of Scotland. When he retired from the editorship he was presented with an address by a representative committee. The following sentences are culled from that address prepared, it may now be revealed, by the late Sir George Macdonald: "To you and to you alone belongs the credit alike for its sterling character and for the regularity of its appearance. Inspired by a genuine interest in the past of your native country, you have given of your best to foster that interest in others, sparing neither time nor money in furtherance of the cause you have so deeply at heart, and bearing almost alone the burden of the whole undertaking." The address also referred to the *Review* as "that storehouse of knowledge of which you have been at once the architect and the warder".

As chairman of the Books and MSS. Committee of the board of trustees of the National Library, Mr. MacLehose, by voice, pen and personal persuasiveness, did much to arrest the destruction or dispersal of family papers of historical and literary value, and ensured their presentation to, or purchase by, the National Library. He was indefatigable. With every inducement to look back over a past packed with achievement, he was, even in old age, when his sight was dim and his natural force abated, ready to live in the present and work, passionately, for the future. "I must home to work while it is called day; for the night cometh when no man can work" might have been his motto, as it was Sir Walter's. The distinguished art of Sir James Guthrie has brought out, most successfully, this eager, forward-looking, vibrant quality in him.

Mr. MacLehose was capped LL.D. of the University of Glasgow in 1915. He was a fellow of the Society of Antiquaries, and of the kindred body in Scotland. He married Mary, daughter of Alexander Macmillan, and is survived by her and by a son and two married daughters. His elder son fell in action as an infantry officer in the War of 1914–18.

W. R. CUNNINGHAM.

Mr. F. S. Marvin

A HISTORIAN with a keen appreciation of the importance of scientific conceptions in the growth of society and a gift for clear exposition passed away in the person of Francis Sidney Marvin, who died on November 14 in his eighty-first year. Marvin was educated at Merchant Taylors' School and St. John's College, Oxford, obtaining a first in Greats and a second in modern history. After teaching for a time in an elementary school, he became one of H.M. Inspectors of Schools, remaining with the Board from 1890 until 1924 and reaching the grade of staff inspector. His chief interest was in history, and from 1915 onwards he organized many courses of lectures for teachers and others. For the session 1929–30 he occupied the chair of modern history in the University of Cairo. After his retirement he was mainly occupied in writing, and in the organization of branches of the Historical Association, to which he frequently lectured.

In August 1914 Marvin was taking part in a meeting of the London Adult School Union at Jordans when war broke out. Feeling that the conception of world history as a unity was sadly lacking, and that this lack had a part in the bringing about of wars, he planned the "Unity History Schools", which met annually, with few interruptions, until the outbreak of the present War. Until 1922 these were held at the Friends' Woodbrooke Settlement, but the 1923 meeting took place in Vienna, and several subsequent meetings were held in Continental cities. Marvin's planning and direction of these schools was admirable. He was most successful in enlisting experts as lecturers, in encouraging discussion, and in summing up the conclusions. A well-grounded classical scholar, he was devoted to the study of history as a continuing record of man's progress. His knowledge of history was wide, but he made no display of erudition, and his style was clear and simple. Although his training had not been in science, he was remarkably successful in seizing the main trends of scientific thought and discovery, which he followed closely, as was shown by his numerous reviews in NATURE of books on sociology and the history of science.

Two of the Unity History Schools dealt specifically with science: that of 1922, when the subject was "Science and Civilization", and that of 1935, when "Science in the Modern World" was discussed in

Rome in a joint meeting with the History of Science Department of the University of Rome. Most of the symposia were published, and some passed through several editions.

An active member of the small Positivist group, Marvin had adopted Comte's teaching that the ladder of the sciences must be completed by sociology. From Comte, too, he had drawn his conviction of Humanity as an ideal, and in recent years, amidst the apparent breakdown of civilization, he never lost his faith in the ultimate triumph of right over wrong.

Marvin's best-known book was "The Living Past", first published in 1913 and several times reprinted. As a comprehensive survey, in which the development of thought is presented as an essential part of history, this short work is perhaps unrivalled. At a dinner in honour of Marvin's seventieth birthday, at which Gilbert Murray, H. G. Wells and others spoke, tribute was paid to his stimulating influence on the study of history. His other books included "Comte" in the series of "Modern Sociologists", "The Century of Hope", "The New Vision of Man", and "The Nation at School". He took an active part in the work of the Sociological Society and its successor, the Institute of Sociology. He married in 1904 Edith May Beverell, and had two sons.

C. H. DESCH.

WE regret to announce the following deaths:

Dr. Walther Kruse, successively professor of hygiene at Bonn, Königsberg and Leipzig and discoverer of the Shiga-Kruse dysentery bacillus, aged seventy-nine.

Dr. F. L. Pyman, F.R.S., director of research, Boots Pure Drug Co., Ltd., on January 1, aged sixty-one.

Mr. Alfred Sidgwick, a distinguished philosopher and logician, on December 22, aged ninety-three.

NEWS and VIEWS

New Year Honours

THE New Year Honours include the names of a number of scientific workers and others associated with scientific work. The principal honours are as follow:

G.C.M.G.: Sir George Gater, Permanent Under-Secretary of State, Colonial Office.

C.H.: The Right Hon. R. S. Hudson, Minister of Agriculture and Fisheries.

K.C.V.O.: Sir Harold Hartley, chairman of the Fuel Research Board.

Knights: Prof. Ernest Barker, emeritus professor of political science in the University of Cambridge; Prof. J. C. Drummond, scientific adviser to the Ministry of Food, professor of biochemistry in the University of London; Prof. F. L. Engledow, professor of agriculture in the University of Cambridge; Dr. J. J. Fox, Government Chemist; Prof. F. R. Fraser, director-general of the Emergency Medical Services; Mr. W. T. Halcrow, engineering consultant, War Office; Mr. C. R. Lockhart, chairman of the East African Production and Supply Council; Mr. T. R. Merton, scientific adviser to the Ministry of Production, formerly professor of spectroscopy in the University of Oxford; Mr. J. G. Nicholson, deputy chairman, Imperial Chemical Industries, Ltd.

C.B.: Mr. P. N. Harvey, director of statistics and intelligence, Ministry of War Transport, Department of the Government Actuary; Mr. C. Nathan, principal assistant secretary, Ministry of Agriculture and Fisheries.

C.M.G.: Right Rev. Mgr. C. Gagnon, rector of Laval University, Quebec, for services to university education; Mr. E. B. Hosking, chief native commissioner, Kenya; Dr. R. C. Wallace, principal and vice-chancellor of Queen's University, Kingston, Ontario, for services to university education.

C.I.E.: Colonel R. H. Phillimore, superintendent of the Survey of India; Mr. M. Carbery, director of agriculture, Bengal; Sri Pattipati H. Rama Reddi, director of agriculture, Madras; Mr. D. B. Sothers, chief conservator of forests, Bombay.

C.B.E.: Mr. W. A. Akers, a director of research, Department of Scientific and Industrial Research; Prof. C. H. Best, professor of physiology in the University of Toronto, for important medical research; Major R. F. Brebner, chairman of directors, Highland and Agricultural Society; Dr. A. N. Drury, director of the Lister Institute, lately a member of the scientific staff of the Medical Research Council; Dr. W. H. Glanville, director of the Road Research Station, Department of Scientific and Industrial Research; Prof. D. A. L. Graham, professor of medicine and clinical medicine and dean of the Department of Medicine, University of Toronto, formerly president of the Royal College of Physicians and Surgeons of Canada, for important medical research; Dr. H. W. Meikle, H.M. historiographer in Scotland and librarian of the National Library in Scotland; Mr. W. Nairn, president of the Royal College of Veterinary Surgeons; J. M. Stewart, K.C., of Halifax, Nova Scotia, for services to university education and also as coal controller; C. Vaillancourt, of Levis, Quebec, for services to war finance and agriculture.

Royal Society Meeting in India

ON January 3, the Royal Society of London convened a short session at the University of Delhi prior to the opening of the Indian Science Congress by the Viceroy of India, Lord Wavell. This is the first time during the nearly three hundred years of its existence that the Royal Society has held a meeting outside London. Prof. A. V. Hill, who is visiting India in connexion with scientific aspects of the war effort, had been appointed vice-president for the occasion. Thus was he able to convey the greetings and goodwill of the President and Council of the Royal Society to the scientific workers of India. The King, who is Patron of the Royal Society, was represented by the Viceroy. There were Indian fellows of the Royal Society present and a large number of guests. Prof. Hill read greetings from the Prime Minister and General Smuts; also from other British scientific bodies. After his address, two recently elected Indian fellows of the Royal Society, Dr. H. J. Bhabha and Sir Shanti Bhatnagar, signed their obligation to the Society on a sheet of parchment which will be inserted in the Society's Charter Book.

British Cotton Industry Research Association : Sir Robert Pickard, F.R.S.

SIR ROBERT PICKARD has for so long been a figure in scientific and educational circles that his retirement, with the close of 1943, from the directorship of the British Cotton Industry Research Association marks something of an epoch. It is seventeen years since he was appointed to succeed the first director, Dr. Crossley, at the Shirley Institute, and all that time it has been his endeavour and pride to build it up until to-day it is the splendid organization that we know, with a staff of more than three hundred and fifty, including eighty graduates. The Cotton Research Association was Sir Robert's particular interest, the child that he brought to vigorous manhood, but he has been a champion of co-operative research associations in general, and it is a question whether any other man has done more for the movement. He was the first director of the British Leather Manufacturers' Research Association before he went to the Shirley, and he has served besides on the councils of two other research associations. It is good to learn that his retirement does not mean that his services to industrial research will be lost entirely, for, doubtless among other activities, he will still be retained as a consultant by both the Associations he has directed.

Sir Robert's connexion with education goes back years even before his research association days. He has been principal of Blackburn Technical School (1907–19) and principal of the Battersea Polytechnic (1920–27), and he has been a member of the Consultative Committee of the Board of Education, a member of the Senate of the University of London since 1926, and has held the office of vice-chancellor of the University of London. A distinguished chemist, he has also played his part in the councils of his chosen subject, having served as vice-president of the Chemical Society, and as president both of the Royal Institute of Chemistry and of the Society of Chemical Industry.

Dr. F. C. Toy

DR. F. C. TOY, who succeeds Sir Robert Pickard as director of the British Cotton Industry Research Association, has been deputy director since 1930, and it is a source of pleasure that he is thus enabled to continue and extend the work he has shared with his chief. Dr. Toy is a physicist, educated at Launceston College, Cornwall, and University College, London, of which he is a fellow. He is well known in Institute of Physics circles, being a member of the Board, the Institute's representative on the National Committee for Physics of the Royal Society, and also chairman of the Manchester and District Branch. He served in the War of 1914–18 as an officer in the Royal Engineers, mainly on sound ranging, afterwards becoming chief physicist to the British Photographic Research Association, where for ten years he was occupied in fundamental researches on the mechanism of the photographic process.

Dr. Toy firmly maintains this fundamental outlook acquired in his earlier days, and he enters upon his new duties with the conviction, based on the experience of the whole of his research life, that pure, long-range investigations constitute more than ever an essential part of the work of any co-operative research organization. This is heartening knowledge for those who recognize where lies the future welfare of British industry, and their good wishes go with the new director of the Shirley Institute as one who not only has helped to form its high scientific character but also is deeply concerned to uphold it.

Action of the Germans in the U.S.S.R.

ON behalf of the Soviet Scientists Antifascist Committee, V. Komarov, president of the Academy of Sciences of the U.S.S.R., A. Bogomolets, president of the Ukrainian Academy of Sciences, and several members of both academies, have sent a message to the Faraday Society, in the course of which they record some of the devastation which has been the regular accompaniment of the German retreat in the U.S.S.R. "Wherever the German army has been, it has brought death and slavery to the people, and destruction of culture." Prof. Nikolai Burdenko, of the Academy of Sciences, U.S.S.R., who personally investigated the crimes of the Germans in the city and district of Orel, refers to the state of psychological stupor of both victims of the German occupation and of medical men treating them. Referring to the material damage, it is stated that when they retreated from Smolensk, the Germans burned down the Teaching, Nutritional and Agricultural Institutes, destroyed the Finance, Co-operative, and Railway Technical Institutes, and the Institute of Telegraph and Telephone Communications, and looted valuable collections from Smolensk museums. In the town of Staline, they wrecked the Medical Institute and burned down all the buildings of the Industrial Institute where 15,000 students studied. In Kiev, a number of large buildings, among them the University, with its library, museums and laboratories, were destroyed. All the Kiev museums, libraries, archives, laboratories and research institutions were looted, according to Alexander Palladin, vice-president of the Ukrainian Academy of Sciences. Prof. Alexander Brodsky, of the Ukrainian Academy of Sciences, states that the Germans blew up and burned the Mining Institute, with its library, at the University Institute of Applied Chemistry, and looted and destroyed a number of other research institutes at Dnepropetrovsk. Prof. Peter Budnikov, of the Ukrainian Academy, who visited Kharkov, states that the Germans destroyed the Institutes of Applied Chemistry and of Electrotechnical Engineering, and other institutes.

The message was received at the annual general meeting of the Faraday Society, and by the authority of the Council, and at the wish of those members of the Society who were present, the following reply was sent : "The members of the Faraday Society have received your tragic message with horror and profound sympathy. The Society will do its utmost to bring it to the notice of all scientists and intellectuals of the United Nations to the end that civilization shall be protected and justice be meted out to the barbarians. E. K. RIDEAL (President), G. S. W. MARLOW (Secretary)."

Scientific Personnel in the Aircraft Industry

THE seventeenth report of the Select Committee on National Expenditure for the session 1942–43, containing replies from Government departments to recommendations in reports, includes a memorandum by the Ministry of Labour and National Service commenting on the Committee's recommendations in its tenth report, discussing aircraft production, on the supply of scientific and technical personnel. The memorandum states that the facilities available for

training research workers, aeronautical engineers and other technicians are under continuous review by the Technical Personnel Committee. It is agreed that men with postgraduate research and similar qualifications should not be allowed to enter the Forces, except for special commissioned posts, for example, operational research. The allocation and deferment arrangements of the Ministry of Labour are considered to provide ample safeguards for this purpose. A professional engineering or scientific qualification is, however, essential for many commissioned posts in the Fighting Services, and in view of the recommendations of Sir William Beveridge's Committee on the Use of Skilled Men in the Services, it has been recognized that a substantial proportion of technical officers in the Services in charge of maintenance and repair of equipment should possess technical qualifications of a university degree or professional standard together with extensive practical experience. But the numbers thus made available were insufficient. It has therefore been necessary to allocate a substantial proportion of the university output to the Services, and also to withdraw experienced men from industry; many of the latter have been volunteers, and the Ministry is concerned lest the Select Committee's observations should be misunderstood, with unfortunate effect on such volunteering.

Steps have also been taken to increase the supply of men graduating in technical subjects by means of the State bursaries, the intensive Higher National Certificate and the Engineering Cadetship schemes. Courses at universities have been shortened to a maximum of two years and three months (two years and nine months in Scotland), and by these measures the output has been substantially increased since 1941 and will reach a peak in 1944. In view of these shortened courses, the Technical Personnel Committee considers that specialized pre-graduate aeronautical courses could be extended only at the expense of fundamental engineering training. The needs of the industry during the War can best be met by the continuation of the existing pre-graduate engineering courses. Apart from a small number of the most promising men who can benefit by a special postgraduate course in aeronautics, graduates should proceed at once to aircraft establishments or firms where they can specialize and pull their weight at the earliest possible moment.

Health in Industry

A MAJOR problem brought to the fore during this War has been to bridge the gulf between scientific knowledge and its application. The Industrial Health Research Board has, during the last twenty-five years, published more than eighty reports on industrial conditions in relation to the health and well-being of the workers. Unfortunately, the necessity for publishing all the data, so that other workers in this field could know what exactly was the evidence on which the conclusions were based, rendered them of little use to those concerned with organizing industry. To remedy this, pamphlets are to be issued giving the conclusions in more general form, and No. 1, called "Ventilation and Heating; Lighting and Seeing", has just been published (H.M. Stationery Office, price 3*d*).

The first part deals with the need for ventilation, the amount of fresh air required, air movement and its problems, some effects of high temperatures, and the complications due to the black-out. The second part gives the principles of good factory lighting, how to measure light, and how the factory regulations should be interpreted, so as to ensure a good general appearance of cheerfulness as well as sufficient light to see the work. Good lighting alone cannot, however, prevent eye-strain for certain kinds of work, so there is a simple account of the working of the muscles of the eyes and of the relief to be secured by the use of special spectacles. There are illustrations showing different systems of artificial lighting, examples of undesirable as well as desirable systems. One undesirable method is called "Glare and Gloom". The pamphlet contains much useful scientific information expressed in readable form.

Measurements at Radio Frequencies

FOLLOWING the annual general meeting of the Radio Society of Great Britain held on December 18, Dr. R. L. Smith-Rose gave a lecture on "Measurements in Radio Experimental Work". After referring to the part played by amateur observers and experimenters in sciences such as astronomy and meteorology as well as in radio, Dr. Smith-Rose emphasized the importance of carrying out quantitative measurements in an orderly and systematic manner. A brief review then followed of the present position in the national laboratories of Great Britain and the United States, of the absolute electrical standards of current, inductance and resistance, and of the practical working standards which are derived therefrom. Frequency is one of the absolute electrical standards common to all branches of electrical engineering, from the low frequencies of the power engineer to the highest used in the modern applications of radio technique: and it is noteworthy that the precision of frequency measurement far exceeds that attainable in the determination of any other radio or electrical quality. With the possible exceptions of current and voltage, most measurements at radio frequencies, such as impedance, resistance and reactance, are made by reference to direct current or low-frequency standards. The lecture concluded with a brief description of some investigations illustrating the application of certain types of measurements at radio frequencies to the determination of the mode of transmission of electric waves along the earth's surface.

Determination of Polar Diagrams of Radio Antennæ

AN article by H. Paul Williams (*Elec. Comm.*, **21**, No. 2; 1943) describes a machine which enables one to determine a polar diagram in a fraction of the time required by direct calculation. A computation which ordinarily would take a whole day can be performed in fifteen minutes on the machine. In its present version, it will calculate the polar diagram given by as many as five antennæ. These may be situated anywhere within a circle of four wavelengths diameter, while the currents in the antennæ may have any relative phases and magnitudes. The exploring angle is read off from a dial marked in degrees, and the corresponding relative amplitude is shown directly on a voltmeter. As few or as many readings as one likes can be taken, and also one may turn the handle backwards to a previous value if required.

With such a machine there is an appreciable reduction in the possibilities of errors—a feature quite as important as the saving of time. It is now also practicable to consider a large number of variations in a design the working out of which would take a prohibitive time without such a machine. Although

the number of antennæ catered for in the present model is five, the principle of operation will allow for its extension to any number. Moreover, the system could readily be extended for tracing out the polar curve automatically. For this refinement all that is required is a turn-table, which would be operated off the common main shaft, and a recording type voltmeter. The machine has been in constant service for about two years.

The Practice of Spraying

GROWMORE BULLETIN No. 9 ("Orchard Spraying for Commercial Growers". H.M. Stationery Office. Pp. 14. 4*d*. net) condenses a large amount of modern knowledge into useful practical suggestions for the spraying of fruit trees. Much of the text relates to the routine care of equipment in order to avoid replacement during war-time. Adjustment of the angle of spray cone to give good average coverage without wind loss conserves spray fluid and saves time. Modern research stresses the necessity for high-pressure spraying, and the corresponding variations in equipment and practice receive full treatment in the bulletin. Mr. J. Turnbull is the author, and much information about the economics of large-scale spraying is included.

Typhus in Venezuela

THE May issue of the *Boletin de la Oficina Sanitaria Panamericana* contains a note on this subject by Dr. L. Briceno-Iragorry, of the Laboratory of Epidemiology of the Venezuela Institute of Hygiene, who states that the first mention of typhus in Venezuela was in March 1896. Since then several cases have been reported in 1938, 1939, 1940 and 1941. The chief forms of the disease in Venezuela may be reduced to two, the first being named Guacaraja fever, which probably resembles Rocky Mountain spotted fever, and the second being known as benign, endemic or rat-borne typhus. The rat-borne character of this second form of typhus has been demonstrated by the Weil-Felix reaction in the blood serum of patients as well as in rats in the Caracas area.

Chronic Parasitoses in Bolivia

IN a recent paper (*Bol. Of. San. Panamericana*, **22**, 487 ; 1943) Dr. Felix Veintemillas, of the Bolivian Institute of Bacteriology at La Paz, states that no systematic study of chronic parasitoses, such as leishmaniasis, yaws, intestinal parasites, dysentery, Chagas's disease and pinto in the tropical and sub-tropical regions has so far been made, although some progress has been achieved. The Bolivian 'azulejos' has recently been identified with pintos, and the first case of granuloma coccidioides was diagnosed in 1941. So far, however, human cases of Chagas's disease have not been found, but infested vectors have been discovered.

Sir Henry Morris, Bart. (1844–1926)

SIR HENRY MORRIS, an eminent London anatomist and surgeon, was born at Petworth, Sussex, on January 7, 1844, the son of a local surgeon. He was educated at Epsom College, of which he afterwards became treasurer, University College, London, and Guy's Hospital, where he qualified in 1861. He first became attached to the Middlesex Hospital in 1870 as surgical registrar, and afterwards became assistant surgeon, then surgeon and in charge of the cancer wards. In 1871 he was lecturer to the Hospital on practical surgery, and during 1872–81 lecturer on anatomy. He retired in 1905 at the age of sixty. He was a prolific writer. His most important work was "The Anatomy of the Joints of Man", which was first published in 1879 and ran through eight editions. In 1893 he became editor of "A Treatise on Human Anatomy", to which he contributed the section on "The Articulations". This work also went through several editions. Besides numerous articles in medical journals and text-books, he was author of several works on genito-urinary surgery. He held many offices at the Royal College of Surgeons, of which the most important were president (1906–7), Hunterian Orator (1909) and member of the Court of Examiners (1894–1904). He died after a short illness on June 14, 1926.

Announcements

MR. R. W. MARSH, of the Long Ashton Research Station, has been elected president for 1944 of the British Mycological Society.

A SOVIET scientific commission is now in Novosibirsk, organizing a Western Siberian branch of the Academy of Sciences of the U.S.S.R. The Academy will establish four institutes in the city : for chemistry and metallurgy, mining and geology, medicine and biology, and transport and power.

EARL DE LA WARR, chairman of the Agricultural Research Council and director of home flax production at the Ministry of Supply, is making a tour in Canada to speak to audiences throughout the Dominion about the war-time agricultural effort in Great Britain ; he will also visit various agricultural institutions in the Dominion, including research stations.

A LECTURE on a chemical engineering subject has been endowed by Mr. J. Arthur Reavell, and will be given under the auspices of the Institution of Chemical Engineers. It will be known as "The J. Arthur Reavell Lecture", and will be delivered not less frequently than once in every four years.

THE following appointments have been made in the Colonial Service : B. J. Hancock, agricultural officer, Gold Coast ; D. A. McBurney, agricultural officer, Sierra Leone ; C. C. Parisinos, agricultural officer, Northern Rhodesia ; R. M. Palmer, assistant conservator of forests, Sierra Leone ; J. R. G. Watters, assistant conservator of forests, Nigeria ; A. L. C. Thorne, veterinary officer, Gold Coast ; C. A. Cockshott, inspector of plants and produce, Gold Coast ; J. H. Henderson, physiological laboratory superintendent, Nigeria ; E. H. Probyn (assistant conservator of forests, Nigeria), assistant conservator of forests, Sierra Leone.

THE third conference on "X-Ray Analysis in Industry" has been provisionally arranged to take place in Oxford on March 31 and April 1 under the auspices of the X-Ray Analysis Group of the Institute of Physics. Particulars can be obtained from Dr. H. Lipson, honorary secretary of the Group, c/o Crystallographic Laboratory, Free School Lane, Cambridge. The conference will be open to all interested, but it may be necessary to limit the number of non-members of the Group for whom accommodation can be provided.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Recognition of a Further Common *Rh* Genotype in Man

SINCE the publication of a recent communication[1] on the subject of *Rh* genotypes certain advances have been made. The point had been reached, as described in that communication, where by the use of three different forms of anti-*Rh* sera, the genotypes of about 68 per cent of the population could be recognized, and five allelomorphs could be distinguished. Since then we have found a serum, described at a meeting of the Royal Society of Medicine on November 2, 1943, which, when used in combination with the other three, makes recognizable the genotype of about 80 per cent of people and defines two further allelomorphs, making seven in all. More recently a letter (see below) has come from Wiener describing all these allelomorphs except *Rhy*. We will use Wiener's names, which are Rh_1, Rh_2, *rh*, *Rh′* (*rh* dot), *Rh″* (Rh_x), but for the gene Wiener calls *Rh* (Rh_1 bar) we prefer Rh_0, for *Rh* has for so long had a much wider meaning. The names we have used[1] and are now abandoning are given in brackets. *Rhy* we will continue to use.

The new serum agglutinates the red cells of people who have the frequent gene Rh_1 or the rare gene *Rh′*. It is undoubtedly the type of serum called by Wiener[2] anti-Rh_1. Perhaps its greatest use is in separating the genotypes Rh_1Rh_2 (12 per cent), Rh_1Rh'' (1 per cent) and Rh_2Rh' (0·2 per cent) from the serologically indistinguishable group called "the rest" in our previous communication. "The rest" group now contains only Rh_2rh (12 per cent) and Rh_2Rh_2 (2 per cent) of common genotypes while, ignoring the rare ones, the genotypes of about 80 per cent of people can be recognized.

We were first made aware of the existence of the forms Rh_0 and *Rh′* when the blood of 154 unselected donors was tested with *Rh St KJ* and anti-Rh_1 sera. Of these, 57 gave the reaction of Rh_1rh (+ + –), all of them being positive with the new anti-Rh_1 serum except one. The presumption that the factor responsible for this unexpected reaction, now called Rh_0, is allelomorphic is supported by its occurrence in two generations of a family (father *rhrh*, mother Rh_0rh, daughter Rh_0rh). Rh_0rh cells give the double dose effect[1] when titrated with *St* serum, showing that Rh_0 is *St*+. Twenty of the 154 bloods gave the reaction of *rhrh* (– + –); of these all were negative with the anti-Rh_1 serum except one; the gene responsible for the exception is now called *Rh′*. In one family (No. 15, Race *et al.*[3]) this allelomorph has been found in two generations (mother's sister *Rh′rh*, mother *Rh′rh*, father Rh_1rh, first child Rh_1rh, fourth child *Rh′rh*). *Rh′rh* cells give the single dose effect when titrated with *St* serum, showing that *Rh′* is *St*–.

The total number of unselected bloods examined with *Rh*, *St* and *KJ* is now 435, and the last 154 of these have also been tested with the anti-Rh_1 serum. This latter serum is supporting the general theory put forward in the previous communication, for in the group *Rh*+*St*+*KJ*+ called "the rest", it can be calculated that 47 per cent should have either the gene Rh_1 or *Rh′*. In the 154 bloods there were 48+++, and of these 20, or 42 per cent, were positive with the anti-Rh_1 serum ($\chi^2 = 0{\cdot}49$ for 1 *D.F.* Probability about 0·5).

The results with the three sera are:

	– + –	+ – –	+ + –	– + +
Mainly	*rhrh* (96%*)	Rh_1Rh_1 (96%)	Rh_1rh (97%)	*Rh″rh* (97%)
	75	75	149	4
Per cent	17 24	17·24	34·25	0 92

	+ – +	– – –	+ + +	Total
Mainly	Rh_1Rhy (100%)	*Rh′Rh′* (100%)	The rest	
	3	0	129	435
Per cent	0 69	0	29·66	

* The figure in brackets shows, in the first case for example, the percentage of bloods reacting – + – which are in fact *rhrh*; the remaining 4 per cent are *Rh′rh*.

The gene frequencies given in the previous communication need slight alteration. Before calculating the frequency of *rh*, a deduction must be made from the 17·24 per cent – + – bloods, since one person in 154, or 0·65 per cent, previously thought to be *rhrh*, is now known to be *Rh′rh*. The gene frequency of *rh* is $\sqrt{0{\cdot}1724 - 0{\cdot}0065} = 0{\cdot}4073$; $Rh'rh = 0{\cdot}0065$; therefore $Rh' = \dfrac{0{\cdot}0065}{2 \times 0{\cdot}4073} = 0{\cdot}0080$. The frequency of Rh_1 can be calculated from the + – – group, of which Rh_1Rh_1 makes up 96 per cent, the remaining 4 per cent consisting of Rh_1Rh' (see Table 2), consequently:
$(Rh_1)^2 + 2(Rh_1Rh') = 0{\cdot}1724$, and since $Rh' = 0{\cdot}0080$, then $Rh_1 = 0{\cdot}4073$, by chance the same as *rh*. $Rh_1Rhy = 0{\cdot}0069$.

$$\therefore\ Rhy = \frac{0{\cdot}0069}{2 \times 0{\cdot}4073} = 0{\cdot}0085;\quad Rh''rh = 0{\cdot}0092$$

$$\therefore\ Rh'' = \frac{0{\cdot}0092}{2 \times 0{\cdot}4073} = 0{\cdot}0113;\quad Rh_0rh = 0{\cdot}0065$$

$$\therefore\ Rh_0 = \frac{0{\cdot}0065}{2 \times 0{\cdot}4073} = 0{\cdot}0080,$$

and by difference $Rh_2 = 0{\cdot}1496$.
Based on these gene frequencies, the expectation for the group + + – and for the group called "the rest" can be calculated, and the theory tested by comparison with observation.

	+ + –	"The rest"
Expected	34·50%	28 63%
Observed	34 25%	29·66%

The frequency of the commonest six genotypes as calculated from our sample are given below. These frequencies are only approximate for the community as a whole, the proportion of *Rh* negative being slightly higher than we have found in a much larger sample.

TABLE 1.

	Per cent	*Rh*	*St*	*KJ*	Rh_1
rhrh	16·59	–	+	–	–
Rh_1Rh_1	16·59	+	–	–	+
Rh_1Rh_2	12·19	+	+	+	+
Rh_1rh	33·18	+	+	–	+
Rh_2rh	12 19 }	+	+	+	–
Rh_2Rh_2	2·24 }				

These total 93 per cent; the remaining 22 rarer genotypes make up 7 per cent, and ignoring these we are able to distinguish serologically between all the 93 per cent, except that we cannot make the distinction between Rh_2rh and Rh_2Rh_2. Examination of thirty families has so far revealed no exception to this scheme of allelomorphs.

This was the state of our work when a letter, dated October 11, 1943, came from Wiener enclosing the typescript of a paper then in the press, in which is described the behaviour of six allelomorphs of the *Rh* gene. In Table 2 is a comparison of Wiener's scheme and our own:

Table 2.

Wiener Antisera Genes	Rh	(St)	Rh_2	Rh_1	Rh'	Rh''
Rh_1	+	0	—	+	+	+
Rh_2	+	0	+	—	+	+
Rh	+	0	—	—	+	+
Rh'	—	0	—	+	+	—
Rh''	—	0	+	—	—	+
rh	—	0	—	—	—	—

Race, *et al.* Antisera Genes	Rh	St	KJ	Rh_1
Rh_1	+	—	—	+
Rh_2	+	+	+	—
Rh_0	+	+	—	—
Rh'	—	—	—	+
Rh''	—	+	+	—
rh	—	+	—	—
Rhy	?	—	+	?

The two schemes show complete agreement, save that Wiener has not met the Rh_y allelomorph because he has not had an *St* serum. The results are so strikingly similar that the probability of their being correct must be very high. We were stimulated by Wiener's letter to attempt to identify his types of sera with those we have used, and have found all of them represented in our collection. Among sera which have occasionally given anomalous reactions, we have been able to identify anti-Rh' and anti-Rh''. That we had not employed these two types of serum regularly does not seem to matter since the distinctions they make are already made by anti-*Rh*, *St*, *KJ* and anti-Rh_1. The great value of *St* serum is made clear, for ignoring those that are very rare, it raises the proportion of people whose genotypes are recognizable from approximately 30 to 80 per cent. While these schemes cover the great majority of our findings occasional anomalous results suggest that other very rare forms may exist.

Phenogenetic Evidence for the Amphidiploid Origin of New World Cottons

THE genus Gossypium may be divided cytologically into four main groups :

(1)	Asiatic diploids	($n = 13$)
(2)	American diploids	($n = 13$)
(3)	Australian diploids	($n = 13$)
(4)	New World 'tetraploids' .. .	($n = 26$)

Cytological evidence[1,2] suggests strongly that New World cottons have been evolved by amphidiploidy from hybrids between Asiatic and American diploid cottons. It is supported by artificial syntheses of amphidiploids which produce partly fertile hybrids when crossed with New World types[2,3]. Phenogenetic evidence leading to the same conclusion is presented here.

It is known that Asiatic and New World cottons each have a series of multiple alleles which control the shape of the leaf. That a similar series occurs in American diploid cottons is highly probable, though critical data are not yet available. If New World cottons are amphidiploids of Asiatic × American diploid parentage they should have (at least initially) *two* leaf-shape loci, one homologous with the Asiatic alleles, the other homologous with the corresponding series in American diploids. Phenogenetic studies of the action of the leaf-shape alleles on the development of the leaf led to the suggestion[4] that the joint action of an entire (unlobed) leaf gene from the

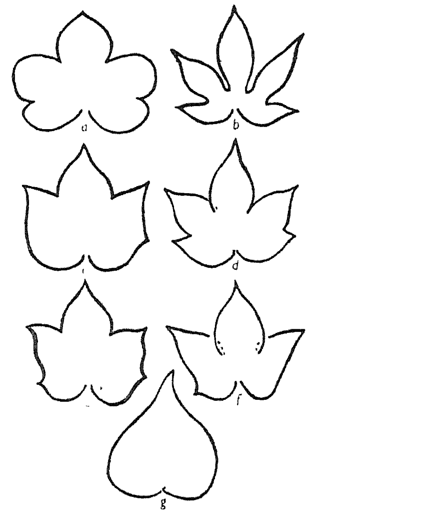

Fig. 1. TOP ROW ASIATIC PARENTS, (*a*) *l* (*herbaceum*), (*b*) L^A (*arboreum*); SECOND ROW: ASIATIC × AMERICAN F_1s, (*c*) *l* × *raimondii*, (*d*) L^A × *raimondii*; THIRD ROW: NEW WORLD AMPHIDIPLOIDS, (*e*) *l* (*hirsutum* VAR. *taitense*); (*f*) L^E (*barbadense* VAR. *darwinii*); BELOW: AMERICAN PARENT, (*g*) *raimondii*.

American diploid parent and a lobed leaf allele from the Asiatic parent might reproduce a type of leaf development which is characteristic of New World cottons. In other words, the New World allelomorph series might be regarded as a series of Asiatic alleles acting in conjunction with an entire leaf gene at the other locus. No duplicate leaf-shape genes are known in New World cottons, so it was postulated, on this hypothesis, that the entire leaf gene is quite stable and common to all New World cottons.

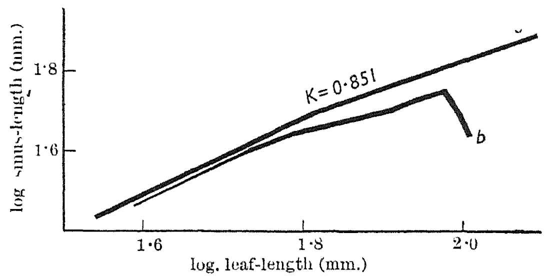

FIG. 2. DEVELOPMENTAL TRACKS OF ASIATIC × *raimondii* F_1 HYBRIDS: (*a*) *l* × *raimondii*, (*b*) L^A × *raimondii*.

Crosses between Asiatic and American diploid cottons very rarely set viable seeds (less than 0·5 per cent in my experience). However, two hybrids have so far been obtained :

	Asiatic		American
(1)	*G. arboreum* (L^A)	×	*G. raimondii*
(2)	*G. herbaceum* (l)		

The symbols refer to the leaf shape alleles carried by the Asiatic parents. The American species has entire leaves. Leaf outlines of the parents and hybrids are compared with standard New World types in Fig. 1. It can be seen that the leaves of F_1, L^A × *raimondii*, and F_1, *l* × *raimondii*, show a marked resemblance to the New World L^E and *l* leaf types, respectively. This resemblance is not a chance superficial one since the course of development is remarkably similar. Developmental tracks* of the F_1 compounds closely resemble those of the corresponding New World types (Figs. 2 and 3). The corresponding *l* × *raimondii* (Fig. 2) and *l* (Fig. 3) tracks are almost linear and

* Graphical representations[4] of the progressive change in leaf shape from node to node during the juvenile stages.

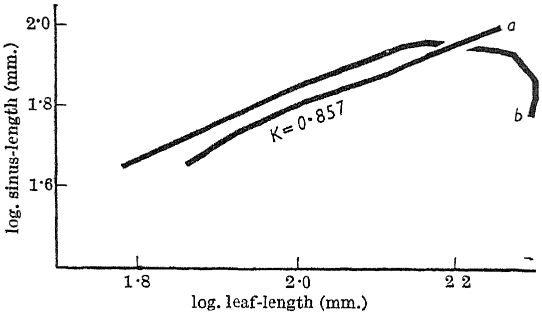

FIG. 3. DEVELOPMENTAL TRACKS OF NEW WORLD AMPHIDIPLOID TYPES: (a) *l*, (b) L^E. COMPARE WITH SYNTHESIZED TYPES IN FIG. 2.

can therefore be expressed as allometric developmental constants (K values). As shown in the figures, the two K values are practically identical.

Subject to confirmation by orthodox genetic analysis—which awaits the successful synthesis by colchicine treatment of a set of amphidiploids which will cross with New World types—the data suggest that two alleles of the New World series, L^E and l, are identical with $L^A + X$, $l + X$ respectively, where X is an entire leaf allele from an American diploid entire leaved ancestor. Four American diploid species with entire leaves still exist: *G. aridum*, *G. armourianum*, *G. klotzschianum* (including *davidsonii*) and *G. raimondii*. General morphological considerations suggest that either of the two last-named in combination with *G. arboreum* would produce a hybrid showing considerable similarity to present-day New World cottons.

Acid-labile Carbon Dioxide in Mammalian Muscle and the Hydrogen Ion Concentration of the Muscle Fibre

FOR the isolated sartorius muscle of the frog it was found[1] that over a wide range of concentration of external potassium and chlorine ions the following relation applied (in accordance with the Donnan principle):

$$\frac{[K]_1}{[K]} = \frac{[Cl]}{[Cl]_1},$$

where $[K]_1$,$[K]$ are the potassium concentrations within and without the fibre, and similarly for [Cl]. It may be assumed that the following would likewise apply:

$$\frac{[K]_1}{[K]} = \frac{[H]_1}{[H]} = \frac{[Cl]}{[Cl]_1} = \frac{[HCO_3]}{[HCO_3]_1}$$

since H is a smaller cation than K, and HCO_3 about the same size as Cl.

Recently Wallace and Hastings[2] published data for the total carbon dioxide in mammalian muscle, finding therein about 11 mM. carbon dioxide per kilo —and allowing the free carbon dioxide to be in approximately equal concentration across the membrane, and the remainder to be altogether HCO_3 ion, it follows that the ratio $\frac{[HCO_3]_1}{[HCO_3]}$ would then be far higher than $\frac{[K]}{[K]_1}$. Therefore, either the mammalian muscle fibre has a much different electrolyte distribution and a different membrane permeability than frog muscle, or the fraction of the total carbon dioxide assigned by Wallace and Hastings to the HCO_3 ions is much too high.

The latter is the true explanation, as shown in recent work in this laboratory. The total carbon dioxide in mammalian muscle was determined by extraction in alkali solution and subsequent measurement of the carbon dioxide liberated on acidification. The figure of Wallace and Hastings was confirmed. It was found, however, that if to the alkaline extract saturated barium chloride was added, and the mixture centrifuged for about 90 minutes at 3,000 rev./min., in many cases a clear solution was obtained, and this contained more than half the total acid-labile carbon dioxide. The leg muscles of very young rabbits, and the abdominal muscle in general, were found to be the most satisfactory for the purpose.

For rabbit abdominal muscle the total carbon dioxide was found to be 11·4 mM. per kilo and the barium-soluble fraction 5·2. For the leg muscle of rabbit and cat the total was found to be 10·6 and the barium-soluble fraction 7·0 mM. per kilo. The reality of a true barium-soluble fraction of such magnitude was proved by the following facts. (*a*) Additions of HCO_3 (as potassium bicarbonate) to the alkali extracts before addition of barium chloride were fully precipitated. (*b*) A curve of turbidity against HCO_3 present before addition of barium chloride was obtained by first evacuating abdominal muscle for hours in the cold, and then extracting with alkali, and adding graded amounts of HCO_3 to similar volumes of extract. The turbidity on adding the barium chloride was measured in the Pulfrich turbidimeter, and expressed in absolute numbers. A value of 0·10 in the extract would about correspond to the barium-soluble carbon dioxide in extract of fresh muscle, whereas either no opacity was present after the barium chloride addition and centrifuging (90 min.) or so little that the total average value was 0·008, or only 8 per cent of the turbidity for the equivalent amount of HCO_3.

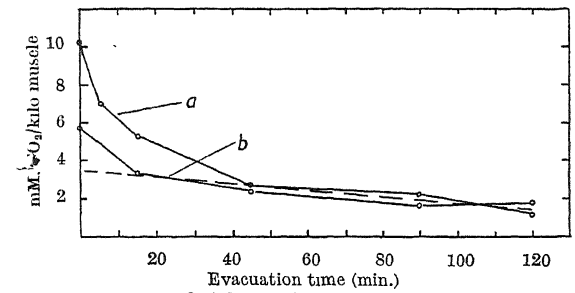
Nature of the barium-soluble fraction. From the researches of Henriques[3], Faurholt[4], Meldrum and Roughton[5], it might be expected that some at least of this barium-soluble fraction is carbamino carbon dioxide. We have investigated the time curve of carbon dioxide loss from evacuated guinea pig muscle, and obtained the mean curves as shown in the accompanying figure. It will appear that a 2–3 mM. fraction only of the barium-soluble quantity is given off rapidly, and the greater fraction, 3–4 mM. per kilo, is emitted very slowly. Only 2–3 mM. can therefore be regarded as likely to be carbamino carbon dioxide, the remainder being a still unknown compound.

The pH in the muscle fibre. The free carbon dioxide plus the HCO_3 ion in leg muscle is $10·6 - 7·0 = 3·6$, and allowing for the interspace values, etc., the true value of the bicarbonate content in the water of the muscle fibre becomes 0·9 mM. per litre, whereas the carbon dioxide in the extracellular water is approximately 1·2 mM. per kilo. Therefore the pH is given by

$$pH = 6·1 - \log 1·2/0·9 = 6·0.$$

If, on the other hand, we consider the ratio

$$\frac{[K]_1}{[K]} = \frac{[H]_1}{[H]},$$



a. Total acid-labile carbon dioxide.
b. Barium-soluble fraction.

and that $[K] = 5{\cdot}5$, and $[K]_1 = 157$, then since the [H] of serum is $10^{-7{\cdot}42}$, we obtain in turn that the value of $[H]_1$ is $10^{-6{\cdot}0}$, or the pH $= 6{\cdot}0$.

In another communication Wallace and Lowry have brought evidence, as they believe, for the non-diffusibility of HCO_3 ion across the muscle membrane. Such experiments are readily interpreted both from the principles outlined for electrolyte equilibria across the muscle fibre membrane and discussed at some length in the *Journal of Physiology* of 1941[6], and the findings here described.

Nitrogenous Manuring of Black Cotton Soil

RAIN-FED cotton is the principal money crop of the black soil tracts of India[1], which are often characterized by low yields and where nitrogen alone, among the three fertilizer elements nitrogen, phosphorus and potassium, has been found to be essential for increasing the yield[2]. Groundnut cake, ammonium sulphate and farmyard manure or compost have all given significant response, the expected increases in yield in pounds of seed cotton per acre for unit dose of nitrogen being $3{\cdot}79 \pm 0{\cdot}22$, $2{\cdot}24 \pm 0{\cdot}17$ and $1{\cdot}19 \pm 0{\cdot}17$ respectively.

Humic manures are slow-acting and do not, in consequence, compare favourably with other nitrogenous manures and fertilizers, at any rate in their immediate effect[3]. But the regular superiority of groundnut cake over ammonium sulphate, even on the immediate crop and, in spite of its slight but significant adverse effect on germination[4], was rather unexpected and warranted further examination. It has since been ascertained that application of groundnut cake and ammonium sulphate to the black, alkaline soil is followed by a certain amount of loss of ammonia, this loss being much more pronounced with ammonium sulphate than with the oilcake. It has been possible to measure, from time to time, the loss of gaseous ammonia *in situ* in field plots by a modification of the technique worked out by Subrahmanyan[5]. Thus, in plots treated with ammonium sulphate and oilcake at 80 lb. nitrogen per acre, the average loss of ammonia from random spots, over a period of 52 days, amounted to 35 and 19 mgm. respectively, the corresponding loss from untreated plots being 12 mgm. In similar experiments carried out in the laboratory, from 12·6 to 24·2 per cent of added nitrogen as ammonium sulphate could be accounted for through loss as gaseous ammonia during a period of a month, whereas, with groundnut cake, under identical conditions, the loss of ammonia ranged only from 8·1 to 16·5 per cent of the added nitrogen.

It would follow, therefore, that a given rate of application of ammonium sulphate would be less effective than its equivalent, on nitrogen basis, of groundnut cake by the extent of its increased loss of nitrogen as ammonia. An observation of interest was that loss of ammonia was considerably less where the ammonium sulphate or oilcake was drilled in furrows instead of being broadcast as is usually the case; such drilling or application at lower depths below the surface was also followed by higher increases in yield[6,7].

Loss of nitrogen from the soil through volatilization as ammonia has been noticed earlier[8,9] and would appear to be a general phenomenon with all tropical soils; indeed, under certain conditions, most of the nitrogen added as ammonium sulphate may be lost in this form within a fortnight[10]. The high alkalinity (pH frequently greater than 9·0) and lime status (replaceable calcium about 40 M.E.) of the black soil would doubtless favour heavy losses of ammonia from this soil, especially with high concentrations of added ammoniacal fertilizers. For this soil, therefore, it is possible that calcium nitrate may prove superior to ammonium sulphate, as has been found to be the case in the Sudan[7].

Nature of the Acid in Soft Water in Relation to the Growth of Brown Trout

As the owner of freshwater fishings in the north of Scotland, I am interested in the growth of brown trout. After making a pH survey of the waters in this area, it soon became evident that this pH reading was of very little use without knowing the factors which determined it, in Nature. Not wishing to be guilty of over-simplification or generalization, I would make it clear that these notes only refer to the natural acid waters as they occur here.

These waters are remarkable for the small quantity of minerals in solution, in many cases not exceeding 2 parts per 100,000. They normally consist of carbonates and bicarbonates of the calcium-magnesium group. I shall refer to this as the calcium content, which is the first of the two controlling factors.

The second is the amount of carbon dioxide in solution. A neutral water, pH 7, under the limitations

above, exists when the calcium content balances the carbon dioxide in solution. An acid or soft water is one in which carbon dioxide is in excess, and conversely a hard or alkaline water has an excess calcium content.

It will be objected that no mention is made of any other acid, mineral or organic. I maintain that there is no proof that any such acid exists in these waters. The generic term 'humic' acid is just a cloak for our ignorance. A. C. Gardiner, I understand, thought that there was a group of such acids, but that they could not be analysed and that they were too weak to effect ionization and consequently did not alter the *p*H. I can find no proof of this view—in fact, many analyses done for me by him appear to contradict it. In any event, if these hypothetical acids are so weak that we cannot detect them, I hold that we may neglect them as not having any possible effect on the ecology of the trout or its food.

During recent investigations (1939–42) a series of tests have been made on the following lines : (*a*) The *p*H of the sample was determined by the colorimetric test and checked by the electrical method. (*b*) Carbonate stability* was ascertained by adding a small quantity of finely powdered chalk to a part of the sample. (*c*) Air free from carbon dioxide was blown through the sample, thus removing the carbon dioxide in solution. (*d*) The *p*H was taken after removal of carbon dioxide. (*e*) The alkalinity of the water, after carbon dioxide had been removed, was determined and reckoned as parts of calcium carbonate per 100,000.

It should be noted that in every case carbonate stability was higher than the alkalinity, and that in no case was any carbonate taken up after the carbon dioxide had been removed. The *p*H was invariably greater than 7 after carbon dioxide had been removed. These facts would appear to indicate that carbon dioxide and not an organic acid is responsible for the initial low *p*H. This conclusion can only be negatived by assuming that the organic acid is too weak to affect the *p*H or to dissolve the powdered calcium carbonate—for which assumption there is no proof; nor if there were, would it be likely to affect the point at issue, namely, the growth of trout. The following table gives a few typical examples, including one of relatively high calcium content.

Sample	Initial *p*H	After CO_2-removal (*p*H)	Alkalinity	Carbonate stability	Uptake of carbonate after CO_2-removal
A	6·0	not read	2·0	3·4	Nil
B	6·2	7·2	2·2	2·6	,,
C	6·2	7·4	2·7	3·4	,,
D	6·0	7·1	1·3	1·8	,,
E	6·6	7·6	10·8	14·1	,,

One of the most frequent causes of acidity is sphagnum moss. If a quantity of this moss is introduced into a neutral or slightly alkaline water, it rapidly produces an acid reaction. This experiment may be repeated a number of times by squeezing the moss nearly dry by hand and adding it to fresh alkaline water, which is in turn made acid. If my theory, is correct, this acidity is produced by carbon dioxide.

Another frequent characteristic of these acid waters is a brown peaty colour, although this is by no means always so. This colour may be largely removed by filtration through fine sand and is due, I believe, to solids in suspension.

The mere presence of acidity due to excess of dissolved carbon dioxide is no bar to the more delicate forms of life. For example, *Gammarus pulex* is found thriving in waters of both high and low alkalinity with an excess of carbon dioxide giving a *p*H less than 6·6.

The result of this investigation might be that we should cease to regard acidity as the inhibiting factor in the quick growth of brown trout, and search rather for some deficiency in these waters. After investigating the question as regards iodine and phosphorus, A. C. Gardiner came to no definite conclusion, and to conclude I would like to quote him[1], whose mastermind we so sadly miss. "The basic question is, why are the trout in these waters so small ? I am all too conscious that there is nothing very helpful in this article, but it may perhaps start a train of thought which, after the war, will result in the launching of an experiment specifically aimed at finding out why."

R. E. SAWYER.

* Carbonate stability is the maximum weight of carbonates, reckoned as parts of calcium carbonate per 100,000, which the water will hold in solution. It is the final alkalinity of the water determined after adding finely powdered chalk.

Detection of the K_α Satellites on X-Ray Powder Photographs

IN the course of recent research on iron-silicon ferritic alloys, a very faint extra line appeared on X-ray powder photographs taken with iron or chromium radiations. The line appeared close to a strong reflexion of high order. The assumption that it was due to an extra phase was eliminated by the fact that the line still appeared when pure elements were used as specimens.

It was then suggested by Dr. H. Lipson that this line could be due to the 'non-diagram' X-ray emission[1], and this has proved to be a satisfactory explanation. To support it, a photograph of carbonyl iron taken in a 19 cm. diameter camera with chromium radiation ($\lambda_{K\alpha 1} = 2{\cdot}28500$ kX. and $\lambda_{K\alpha 2} = 2{\cdot}28889$ kX.) was measured and the wave-length corresponding to the extra-line appearing with the 211 doublet was found to be 2·2736 kX. This is in good agreement with the values published by Parratt[2], who made an

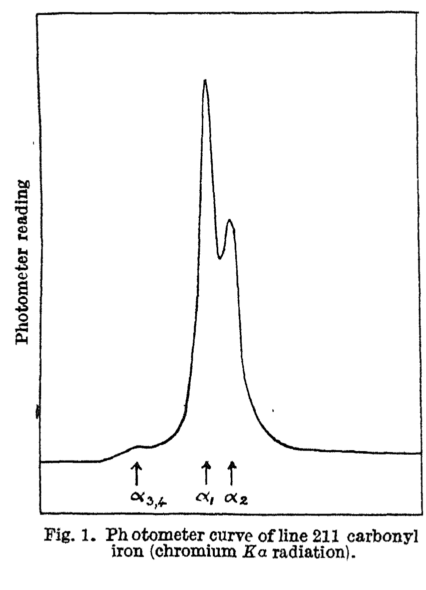

Fig. 1. Photometer curve of line 211 carbonyl iron (chromium $K\alpha$ radiation).

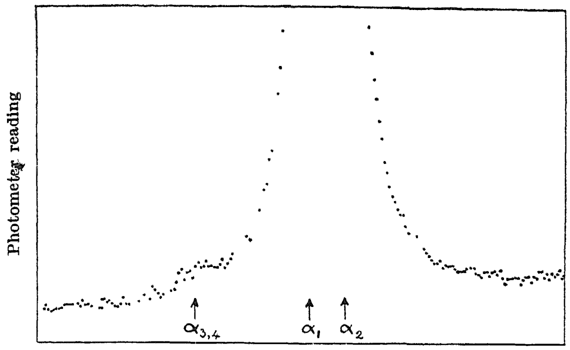

Fig. 2. Experimental points from which Fig. 1 is derived.

extensive study of the $K\alpha$ satellite lines by means of a double spectrometer and an ionization chamber. He found four components for the $K\alpha_3\alpha_4$ group, the two principal ones for chromium having the following wave-lengths: $K\alpha_3 = 2 \cdot 27443$ kX.; $K\alpha_4 = 2 \cdot 27290$ kX. The photometry of the 211 lines confirms the presence of this extra reflexion, as shown by Figs. 1 and 2.

We have detected also the $K\alpha_3\alpha_4$ group with nickel, cobalt and iron radiations, using specimens of pure elements which give a strong high-angle reflexion. The line was weaker with the shorter wave-lengths, in agreement with Parratt's data[2].

To the best of our knowledge, this is the first time that the $K\alpha_3\alpha_4$ group has been definitely detected on powder photographs. The possibility of the appearance of this reflexion, the intensity of which is about 1/100 of the intensity of $K\alpha_1$, should be borne in mind when strong high-angles lines occur on X-ray photographs.

We wish to thank the Director-General of Scientific Research and Development, Ministry of Supply, for permission to publish this note.

Post-War University Education

WHILE possible changes in university education after the War are being considered, I should like to urge the importance of one problem which has hitherto obtained little prominence. Anyone who had much contact with students before the War could not fail to be impressed by the specialized nature of most of their knowledge. For example, a graduate in classics was often completely ignorant of scientific thought, while a graduate in any of the sciences, as a rule, knew little of humanistic subjects beyond some French and German. Moreover, there is little doubt that this increasing departmentalization of the universities was encouraging the tendency, so disastrous at the present time, whereby what is scientific is divorced from humanistic purposes. The regulation at some universities compelling an honours student to take one or two classes outside his honours group, while good in theory, fails in practice, because these other classes are much too narrow in their aims and are, in fact, often the first-year courses for students who propose taking honours in them.

How can this be remedied ? It would be a retrograde step to decrease the specialization of the honours groups, and the proposal of the British Association Committee on Post-War University Education to introduce a new honours group, called "philosophy, natural and social", does not solve the present difficulty, namely, how students, in honours groups which already exist, can acquire a more balanced and mature mental outlook.

The best solution, it seems to me, is the introduction of a course dealing with what is called in the United States "The History of Ideas". Such a course would deal with the growth and development of conceptions which play a great part in our intellectual life to-day—conceptions such as individual freedom, social equality, scientific law, moral obligation, evolution, the nature of scientific method, and so on. At universities where attendance at lectures is, to some extent, compulsory, I should like to see such a course compulsory for all honours students in the year before they sit for their final examination. They would at this stage be more mature than freshmen and yet not be under the strain of working for their degree examination. At universities where attendance at lectures is entirely voluntary, I should like to see those students who did not attend the course compelled to take the examination in it, so that they would at least have been forced to read books like Whitehead's "Science and the Modern World" and Coulton's "Medieval Panorama", and to discuss some of the problems raised by them under the guidance of a tutor. I am urging this step for honours students only. Undergraduates who are reading for a pass degree are at present able to study a considerably wider range of subjects, and the problem is therefore not so pressing for them. Besides, it is most necessary that those who are intellectually the most able should have this broad background against which they can set their own specialized activity.

If the desirability or, as I should prefer, the necessity of such a course is admitted, it would not be difficult to organize it. The best means, I think, would be for it to be given in university departments of education. At present such departments give courses on the history of education, and while these cover to some extent the rather dry topics dealt with by text-books appearing under that title, they deal mainly (or should deal mainly) precisely with the history of those ideas which have had a great influence on the development or education of mankind. It would no doubt mean that the departments concerned would have to make some domestic alterations, but it does not seem that any fundamental changes would be necessary.

It may be objected that the numbers for such a course would be much too large. If that is so, it might be necessary for a few years to limit the number taking it until a large enough staff could be obtained to deal with them. But that is certainly not a permanent objection. I understand, although I have no direct knowledge, that a few years ago it was made compulsory for all Harvard undergraduates to take a course in American history. It seems to me the time is now ripe for all British undergraduates, of sufficiently high intellectual capabilities, to learn the history, not of this or of some other nation, but of what is common to all nations—the ideas which are the basis of the modern world.

C. D. HARDIE.

Gerard Road, Harrow.

RESEARCH ITEMS

Scraggly and Ataxic Pigeons

O. Riddle and N. F. Hollander have described (*J. Hered.*, **34**, 167; 1943) two recessive characters, scraggly and ataxia, in their cultures of pigeons. Scraggly squabs show crusty and flaky skin homologous to ichthyosis in man, and the feathers appear more slowly than normal and do not interlock. Flight is impossible with these hairy-like feathers, which also do not protect the bird from cold. Scraggly behaves as a normal Mendelian recessive in inheritance and shows no linkage with several other characters. Ataxia has been followed for twenty-eight years. It causes the bird to show several inco-ordinations in behaviour; nodding of the head, unsteady gait, somersaulting, irregular flight and sitting on its tail. Histological examination indicates that myelination in the nervous system is reduced and differences in chemical constitution of the cerebrum-medulla segments of the brain are marked. The condition in pigeons has points of similarity with Friedrich's and with Marie's ataxias in man. Ataxia in pigeons is inherited as a Mendelian recessive, but the inheritance is irregular.

Fibrinogen

A CURIOUS property of fibrinogen not exhibited by other serum proteins has been discovered by L. B. Jaques (*Biochem. J.*, **37**, 344; 1943). Study of the clotting of purified fibrinogen by thrombin required, in order to obtain samples for analysis, a method of stopping the reaction quickly which would not affect the solubilities of fibrin and fibrinogen. When dilute iodine, potassium permanganate and potassium dichromate were tested for this purpose they were found to give heavy precipitates with fibrinogen. Both iodine and hydrogen peroxide were reduced by fibrinogen, although with hydrogen peroxide precipitation occurred only in the region of the isoelectric point. This characteristic reduction of iodine and hydrogen peroxide by fibrinogen indicates a further example of the non-sulphydryl reducing groups of proteins studied by Anson and Mirsky. The nature of this group in fibrinogen is unknown, cysteine and ascorbic acid being the only simple substances tested which show similar reducing power, but the negative nitroprusside test suggests that the former is not responsible. It is known that tyrosine and tryptophane reduce iodine in phosphate buffer, and the reducing action may be in some part due to this. Fibrinogen, however, contains a group with much stronger reducing properties than either tyrosine or tryptophane, and the number of such groups apparently increases on conversion of the fibrinogen to fibrin.

Greenland Plants

THE Julianehaab district of south-west Greenland is climatically the most favoured area of that country. It has been many times visited by botanists, and its flora, comprising about 300 indigenous vascular plants, was regarded as one of the best known throughout Greenland. Two months intensive botanizing during the summer of 1937, however, enabled N. Polunin (*J. Linn. Soc.*, **52**, No. 345; Oct. 1943) to add another twenty-one species—exclusive of introduced plants—to the flora of this district. Eleven of these are new to Greenland, the rest being species not previously known to occur so far south. The new discoveries include *Botrychium tenebrosum* Eaton, *Danthonia spicata* (L.) Beauv., *Carex Mackenziei* Krecz., *C. magellanica* Lam., *Gentiana Amarella* L. (Agg.) and *Antennaria compacta* Malte. *Potamogeton natans* L. is also new to Greenland, but the endemic *P. groenlandicus* of Hagström is reduced to *P. Berchtoldii* Fieb. The plant which had previously been recorded from this district as *Equisetum hiemale* L. is now identified as *E. trachyodon* A. Br. In view of the suggestions which have been put forward that the latter is the hybrid *E. hiemale* × *variegatum*, its occurrence in a country from which *E. hiemale* appears to be absent is of considerable interest. This contribution to the flora and phytogeography of south-western Greenland consists of an enumeration of all vascular plants known to grow in the area visited, with critical notes thereon. Students of the British flora will find much of interest and value in the treatment of polymorphic species such as the alpine Cerastia, *Plantago maritima*, *Juncus alpinus*, Poa spp., Carex spp., and others. *Matricaria suaveolens* is one of the score of alien plants added to the already considerable list of introduced species.

Multiperforate Plates in Xylem Vessels of Monocotyledon Roots

VON MOHL described net-like cross walls in the vessels of palm roots, and B. C. Kundu (*Proc. Ind. Acad. Sci.*, **16**, 6; 1942) has now shown that the multiperforate is the only type of vessel segment to occur in the roots of certain Araceæ (Colacasia and Alocasia) and also in Crinum, and they are also of frequent occurrence in *Canna indica*. These roots do not have secondary thickening, so that the scalariform-reticulate vessels in which the multiperforate plates occur are in the protoxylem formed about the time of cessation of growth in length. The occurrence of this type of vessel segment associated with earlier differentiated tracheid-like spiral protoxylem elements is of interest, but does not appear to be the same phenomenon as the less general occurrence of multiperforate plates in vessels of certain relatively specialized, herbaceous dicotyledon shoots such as *Helianthus annuus* and *Heracleum Sphondylium*. They are also so different from the scalariform perforations of certain woody dicotyledons, that it would seem premature to draw conclusions as to the primitive nature of the vessels in these monocotyledonous roots.

Fusarium Wilt of the Carnation

THE fungus *Fusarium Dianthi* causes a serious wilt disease of the carnation crop on Long Island, U.S.A. This malady has been studied by J. M. Bickerton (Bull. 788, Cornell Univ. Agr. Exp. Sta., Ithaca, N.Y., December 1942). Yellowing, stunting and necrosis accompany the wilted condition, and the pathogen is soil-borne. It generally enters the host through the roots and progresses very rapidly into the shoots when temperatures are optimal—about 80° F. Control measures suggested include the selection of healthy cuttings and the use of resistant varieties grown upon fresh soil. Soil disinfection is apparently successful only within the limits of greenhouse benches, and not in the open. It is interesting that, in addition to formaldehyde, the incipient war 'gas' chloropicrin has been found satisfactory for this purpose—a subtle variant of the beating of swords into ploughshares.

Structure of Boron Hydrides

THE structure of the hydrides of boron has been the object of many theoretical investigations and is still somewhat puzzling. H. C. Longuet-Higgins and R. P. Bell (*J. Chem. Soc.*, 250; 1943) have adopted the view that the molecules contain a hydrogen bridge linkage $>B\!:\!\genfrac{}{}{0pt}{}{\cdot H \cdot}{\cdot H \cdot}\!:\!B<$ which is regarded as a resonance hybrid between structures containing only normal electron-pair bonds, and differs from the ordinary type of hydrogen bond. This provides an explanation of the diamagnetic character of B_2H_6 and agrees with the fact that all the boron hydrides contain an even number of electrons. The absence of a direct link between the boron atoms explains the chemical behaviour of the hydrides. The authors discuss the bearing on the hypothesis of the data for the electron diffraction, Raman spectrum, infra-red spectrum and specific heat of B_2H_6, which support a bridge configuration rather than one resembling ethane. Structures for the higher hydrides are suggested.

Synthesis of Adenine

IN the synthesis of adenine by Traube in 1904 from 4 : 5 : 6-triamino-2-thiolpyrimidine the overall yield was poor. J. Baddiley, B. Lythgoe and A. R. Todd (*J. Chem. Soc.*, 386; 1943) describe a synthesis from 4 : 5 : 6-triaminopyrimidine as parent substance, this being obtained by reduction of 4 : 6-diamino-5-benzeneazopyrimidine, formed by the condensation of formamidine with benzeneazomalononitrile. The thioformyl derivative of 4 : 5 : 6-triaminopyrimidine was converted on boiling in aqueous or pyridine solution into adenine, with high overall yield (more than 50 per cent). A comparison of the ultra-violet absorption spectrum of the synthetic product with that of natural adenine showed no divergence. This work makes adenine a readily accessible compound, and similar methods of synthesis could probably be applied in the case of other naturally occurring purines. In another paper, by G. W. Kenner, B. Lythgoe, A. R. Todd and A. Topham (*J. Chem. Soc.*, 388; 1943) some reactions of amidines with derivatives of malonic acid are described, in which some results of other earlier experimenters are corrected.

Constitution of the Solar Corona

A NEW theory of the solar corona has been put forward by H. Alfvén in a paper which has recently reached Great Britain (*Ark. Mat. Astron. Fys.*, 27A, No. 25; 1941). Observational facts have been accumulating for many years that particles exist at or near the sun's surface with energies of perhaps hundreds of electron volts, at any rate far above that corresponding to the photospheric temperature. The hypothesis suggested is that the corona is an atmosphere consisting entirely of such particles. If the light of the corona is regarded as sunlight scattered by electrons which are in equilibrium under gravitation and thermal agitation alone, the observed density function leads to an energy distribution in which the mean energy of the electrons remains almost constant at 180 eV. in the region between 0·2 and 2 solar radii from the surface. This corresponds to a thermal equilibrium temperature of nearly 1·4 million degrees. A very good representation of this state of affairs is found if about 10^{-5} of the solar energy output is used in producing high-energy particles in the upper chromosphere, and if the low density of the corona prevents loss by radiation. A still better agreement with observation is obtained by allowing for the force on the charged particles due to the gradient of the general magnetic field of the sun; in this case the temperature found is about half that for the simpler assumption. The theory explains at least qualitatively the production of the emission lines and their great breadth, and the characteristic ray structure observed near the magnetic poles of the sun.

Stellar Companions of Small Mass

IN an article (*Pub. Astro. Soc. Pacific*, **55**, 79; 1943) H. N. Russell investigates the probable physical characteristics of the quasi-planets recently found in the systems 61 Cygni and 70 Ophiuchi (NATURE, **152**, 66; 1943). The gravitational attraction of these bodies causes perturbations in the motions of their primaries which suggest that they are only about one-hundredth the mass of the sun. On various plausible assumptions as to the chemical composition of such companions, Russell deduces upper and lower limits for their radii and for their internal and surface temperatures. Even at their hottest the companions are probably not self-luminous, though their internal constitution resembles that of a star. Almost certainly most of their light will be that reflected from the primaries. Until about thirty years ago it was believed that Jupiter and Saturn were feebly self-luminous, yet no objections were raised to calling them planets. Probably the newly discovered bodies are much bigger relative to their primaries than the solar planets, but that raises no insuperable objection in nomenclature; before the secondary minimum of Algol was discovered its variation was described as due to eclipses "by an enormous planet". The author concludes that it is well within the bounds of accepted usage to describe the new bodies as planets.

Polyatomic Emission in the Visual Spectra of Comets

CLOSE on the heels of the discovery a year ago that the bands near 4050 A. in cometary spectra are due to the polyatomic emitter CH_2 comes the news that the strong 6300 A. group is probably to be attributed to NH_2. Study of cometary spectra in the visual region has not progressed as fast in the past few decades as the improvement in photographic plates might suggest, mainly because of the lack of fast grating spectrographs and of bright comets. The present work (*Astrophys. J.*, 98, 142; 1943) is the result of co-operative study of the spectra of Comet Cunningham and Comet Whipple II carried out at the McDonald, Dominion Astrophysical and Mt. Wilson Observatories. Wave-lengths are given for the emission features in the spectra of the heads of these comets in the region 4800–7050 A., and possible identifications are discussed. The group of bands at 6300 A., which is the strongest unidentified feature, behaves with respect to heliocentric distance much as the 4050 A. group does. Many coincidences are noted with bands in the spectrum of the ammonia-oxygen flame, and it is suggested that the emitter is a photo-dissociation product of ammonia liberated from the solid constituents of the cometary nucleus. Study of the electronic structure and the energy-level diagram to be expected in NH_2 suggests that this molecule is likely to be the one responsible, particularly as the NH molecule, a product of further dissociation, is known to be well represented in cometary spectra.

THE VETERINARIAN AND THE COLONIES

MAJOR J. M. SMITH, who was formerly chief veterinary officer to the Department of Agriculture and Fisheries, Government of Palestine, recently gave to the National Veterinary Medical Association of Great Britain and Ireland a valuable address on the part played by the veterinarian in the development of our Colonies (*Vet. Rec.*, **55**, 415; 1943).

Colonial development requires, he said, many specialists. The population of the Colonies are usually natives with a pastoral economy, which is sometimes nomadic. Cattle are the wealth of the community, and tribal influence often depends on the number of cattle possessed by the tribe. Improvement of the existing agricultural methods results in more settled communities, better trade and food production and increase in the population, with higher standards of health among the people and their domestic stock. Development of trade requires development of trade routes and of means of transport, and these require further measures of health control. It is clear that the veterinary surgeon taking part in developments of this kind has to adapt himself to conditions very different from those prevailing in the British Isles.

Like the missionary, administrator and the medical man, he must try to understand the people and their customs; he must also study the climate and the wild and domestic animal life. Major Smith says that, after some years of work of this kind, the chief contagious diseases of cattle are being gradually controlled in our Colonies; from some of them they have been eradicated. Parts of Africa, however, still await general development. Not all Colonies give the veterinary officer his due; not all of them realize how useful he can be. Major Smith tells us exactly how he can help the administrator.

His first function must be active work in the field and research in the laboratory on rapidly spreading contagious diseases such as rinderpest, trypanosomiasis, tuberculosis, anthrax and swine fever. The amount of work involved is indicated by the fact that in Nigeria in 1941 433,000 cattle were vaccinated and 182,000 temporarily immunized against rinderpest, while 300,000 were vaccinated against blackquarter and 500,000 against hæmorrhagic septicæmia. By selective breeding, elimination of inbreeding and castration of inferior stock the general level of livestock is being improved. Artificial insemination is being used on a small scale in Kenya and Palestine with encouraging results. Improvement of stock creates demands for movement of stock over great distances, and trade routes for these movements have to be guarded against disease by inspection, regulations and research. When trade in hides, skins, ghee, butter and similar products develops, the veterinary officer must help the native to improve the production of these. In Uganda, for example, the value of exported hides and skins in 1939 was about £90,000; in 1941 it was £140,000. Similar increases have occurred in Kenya and Nigeria. In some Colonies dairying has become a valuable industry. Kenya, for example, produced, in 1940, 3½ million pounds of butter and 300,000 pounds of cheese. The commercialization of the native ghee, made by extracting the fat from milk, has resulted in a large export trade in this for Kenya, Nyasaland and Tanganyika Territory. Other Colonies await similar development.

The export of cattle and meat from Colonies where east coast fever and contagious bovine pleuropneumonia flourish is difficult or impossible; other countries will not import such stock. Some Colonies afflicted with such diseases have, therefore, fallen back on the production or export of canned and frozen meat produced in their own plants. Efficient meat inspection by veterinary officers is demanded by the importing countries and is, indeed, essential to the production of meat for human consumption. To help in this work selected natives are being educated in Kenya and Nigeria in the use of simple veterinary equipment and in the administration of drugs by the mouth and of sera and vaccines and in animal husbandry.

In most of our Colonies, veterinary departments have now been established and these are in no way subordinate either to the agricultural or the medical departments; the pay and conditions of service of their personnel compare favourably with those of the medical, legal, engineering and other professional services. This is as it should be everywhere. Major Smith thinks, however, that the great work being done by the colonial veterinary officer will be greater still in the future. He concludes his address with his views upon these future developments. Among future colonial problems he mentions the tackling of diseases of farm stock which are still causing enormous financial losses at home, and the prevention of the entry of these into our Colonies, improvements in the housing and feeding of animals and in the killing centres and meat production plants, the organization and establishment of dairies and the maintenance of the health of the increased animal populations. The broadening of veterinary education, the co-operation of the universities and the aid of the Government will all be required if we are to educate rightly the right sort of men for this important colonial work.

Contributors to the interesting discussion which followed the address showed substantial agreement and some amplification of it. Among the speakers were Mr. John Smith, adviser in animal health to the Colonial Office; Sir Arthur Olver, principal of the Royal (Dick) Veterinary College; Prof. Kearney of Dublin, and other veterinarians who have had long experience of veterinary administration and practice in Egypt, the Sudan, India, Kenya, Nigeria, West Africa and South Africa. We cannot summarize their remarks here, but it is pertinent to mention Sir Arthur Olver's reference to the work of Sir Arnold Theiler in South Africa and of Dr. Moehler in the United States. The work of both these men, said Sir Arthur, has revolutionized the agricultural industries of both these countries, with enormous economic and social benefit to them. Prof. Kearney, in the course of a speech which illustrated the brilliant successes of the veterinary profession in a comparatively short time, quoted Dr. Julian Huxley's "Africa View". "In Africa," wrote Huxley, "the prosperity and, indeed, the habitability of enormous areas hangs upon his (the veterinarian's) success or failure in research along the broadest biological and medical lines. . . . To be a good veterinary officer in Africa you must be a first-class biologist and you must be a knowledgeable and sympathetic anthropologist as well." These words might well form part of the terms of reference for any committee which is asked to report upon veterinary education in Great Britain or in any other country (see p. 35 of this issue).

ARCHÆOLOGICAL RECONNAISSANCE IN GUATEMALA

THE memoir on "Archæological Reconnaissance in Campeche, Quintana Roo, and Peten", as its name implies*, describes a reconnaissance, comprising four expeditions organized by the Carnegie Institution between 1932 and 1938, which did not include any excavation. The region is densely forested and practically uninhabited, but with the aid of the local knowledge of the chicle collectors the expeditions proved it to be rich in Maya remains. These present many interesting features, which are set out in a short summary. This is followed by a description of individual sites, the geographical position of which is given in each case to the nearest 0·1 minute of arc, a wise precaution in an area where clearings vanish in a few seasons. A section on the monuments, with a useful chronological table, follows. In the introduction to this is described a method of taking rubbings, which may well prove useful to workers elsewhere for the recording of carvings in low relief, provided that the proper type of long-fibred Korean paper can still be obtained. The illustrations, comprising a liberal allowance of plans, sections and photographs, are grouped at the end.

The buildings in the southern area, associated with the Peten, differ in style from those in the north. The southern group has undecorated lower zones, an indentation in each side wall and a slight projection of the central part of the back wall. The northern, or Rio Bec type, has in its most striking instances two or three ornamental masonry towers which rise above the roof, but even where these are absent, it is distinguished by elaborately decorated façades. A restoration drawing of a notable example with three towers at Xpuhil forms the frontispiece of the work. The southern group is dated by means of the stelæ between 8.18.9.17.18 and 10.3.0.0.0, or between the first and seventh centuries A.D. according to Spinden's correlation, but no decipherable dates have yet been found in the northern group, though there is some evidence that they were contemporary.

Parallels to Group E, at Uaxactun, believed to have been a solar observatory, were found in a number of sites in the centre and south of the area. The axial line departs by varying amounts up to 15° from true east, without any apparent correlation with latitude, so it is suggested that the origin of the grouping may be astronomical, but the later examples merely ritualistic.

A particularly interesting vaulted building, unfortunately far from perfect, in which the true arch was almost attained, was found at La Muñeca. Another site, Pechal, seems to have included an amphitheatre. Like the majority of Maya sites, most of those visited were without defences, but one town, Becan, had an elaborate moat, traversed by seven causeways, though it is uncertain whether this was ever completed.

Considering the overgrown nature of the country and the bad state of the monuments, these four short expeditions brought back a great wealth of material, which is admirably presented. Excavation will doubtless follow as soon as it is practicable.

G. H. S. BUSHNELL.

GENEALOGY OF HUMAN FOLLY

SCHOLARS are to-day busy tracing the spiritual antecedents, before Pan-Germanism, of Herr Hitler. Substantial work has shown the linear connexion with Luther. Prof. Collingwood even triumphantly exposed the scalp of an ancestor in the person of Thomas à Kempis. A study of the similarity of Hitler and Mr. G. B. Shaw has yet to be made. The similarity with Carlyle (and dissimilarity with Emerson) is substantial and extensive in the vertical line, when all allowance is made for the fact that Hitler, Carlyle and Emerson are all horizontally men of their time and place.

Prof. MacKeehan, in the most recent issue of the University of Colorado Studies (vol. 2), has made a useful contribution by underlining this. There is a genealogy of human folly as well as of truth. It is well to be reminded that Thomas Carlyle wrote: "Germany, from of old, has been the peaceablest, most pious, and in the end most valiant and terriblest of nations. Germany ought to be President of Europe, and will again, it seems, be tried with that office for another five centuries or so". This indicates the danger of judging any people's policy by the ideas of its literary nabobs. In fairness, however, to Carlyle and Emerson, it should be said that they were more concerned with what is now fashionably called 'the restoration of moral values' than with the nature of leadership.

Prof. MacKeehan's study will have done good work if it deters a few would-be leaders from supplying us with moral reach-me-downs from their nearest peg as poor Carlyle tried to do from the Ecclefechan store. The University of Colorado, always known as a foyer of ideas, is to be congratulated on its enterprise, although I found the "Thirteen Points of Spelling and Punctuation" enjoined on contributors intimidating. I am against standardization alike in printing and politics; and rejoiced when the revolting printer's devil produced the magnificent variant 'virute'.

GEORGE CATLIN.

FORTHCOMING EVENTS

*(Meeting marked with an asterisk * is open to the public)*

Saturday, January 8

GEOLOGISTS' ASSOCIATION (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Mr. C. E. N. Bromehead: "Geology and Health".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Prof. E. N. da C. Andrade, F.R.S.: "Vibrations and Waves", 6: "Long Electromagnetic Waves".*

Monday, January 10

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 8 p.m.—Capt. the Rev. H. R. Rokeby-Thomas: "Islands of the Canadian Arctic".

Tuesday, January 11

SOCIETY OF CHEMICAL INDUSTRY (CHEMICAL ENGINEERING GROUP) (joint meeting with the INSTITUTION OF CHEMICAL ENGINEERS) (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Mr. A. J. Andersen: "The Manufacture of Margarine".

IRON AND STEEL INSTITUTE (joint meeting with the STAFFORDSHIRE IRON AND STEEL INSTITUTE) (at the Dudley and Staffordshire Technical College, The Broadway, Dudley), at 7 p.m.—Mr. J. H. Whiteley: "A Study of Austenitic Grain Growth in Medium-Carbon Steels".

Wednesday, January 12

SOCIETY OF CHEMICAL INDUSTRY (PLASTICS GROUP) (joint meeting with the FARADAY SOCIETY to which the LONDON SECTION OF THE OIL AND COLOUR CHEMISTS ASSOCIATION is invited) (at the Institution of Mechanical Engineers, Storey's Gate, St. James's Park, London, S.W.1), at 2 p.m.—Symposium on "Molecular Weight and Molecular Weight Distribution of High Polymers" (to be opened by Prof. H. W. Melville, F.R.S.).

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 2.30 p.m.—Sir Frank Smith, G.C.B., F.R.S.: "The Story of Petroleum—A Giant of Modern Industry".

Thursday, January 13

CHEMICAL SOCIETY (joint meeting with the SOCIETY OF CHEMICAL INDUSTRY, the ROYAL INSTITUTE OF CHEMISTRY, and the BRITISH ASSOCIATION OF CHEMISTS) (in the Muspratt Lecture Theatre, The University, Liverpool), at 4 p.m.—Prof. E. D. Hughes: "The Reactivity of Organic Compounds".

INSTITUTE OF FUEL (joint meeting with the BRISTOL AND SOUTH-WEST COUNTIES SECTIONS OF THE SOCIETY OF CHEMICAL INDUSTRY, CHEMICAL SOCIETY, and the ROYAL INSTITUTE OF CHEMISTRY) (in the Chemistry Department, The University, Woodland Road, Bristol), at 5.30 p.m.—Mr. G. M. Gill and Mr. John Roberts: "Post-War Coal Processing".

IRON AND STEEL INSTITUTE (joint meeting with the EBBW VALE METALLURGICAL SOCIETY) (at the Rational Hall, Ebbw Vale), at 7 p.m.—Dr. C. H. Desch, F.R.S.: "Research in the Steel Industry".

PHARMACEUTICAL SOCIETY (at 17 Bloomsbury Square, London, W.C.1), at 7 p.m.—Presentation of the Hanbury Memorial Medal to Sir Henry Dale, F.R.S., followed by an address on "The Natural History and Chemistry of Drugs".

Friday, January 14

INSTITUTE OF FUEL (at the Chamber of Commerce, Swansea), at 4 p.m.—Mr. H. R. Horman: "The Production of Producer-Gas and Blue Water Gas".

Saturday, January 15

SHEFFIELD METALLURGICAL ASSOCIATION (at 198 West Street, Sheffield 1), at 2.30 p.m.—Annual General Meeting. Presidential Address.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

SCIENCE MASTER, mainly for CHEMISTRY, up to University Scholarship standard, at the City of London School—The Town Clerk, 55–61 Moorgate, London, E.C.2 (January 12).

CHAIR OF CHEMISTRY—The Principal, University College of Wales, Aberystwyth (January 15).

REGIUS PROFESSOR OF ZOOLOGY at Glasgow University—The Private Secretary, Scottish Office, Fielden House, 10 Great College Street, London, S.W.1 (January 17).

HEAD OF THE DEPARTMENT OF ENGINEERING, Schools of Technology, Art and Commerce, Oxford—The Chief Education Officer, City Education Office, 77 George Street, Oxford (January 19).

UNIVERSITY LECTURER IN ANTHROPOLOGY—The Secretary of the Appointments Committee, Faculty of Archæology and Anthropology, Museum of Archæology and of Ethnology, Cambridge (April 15).

ASSISTANT LECTURER IN CHEMISTRY, PHYSICS AND BOTANY—The Principal, Swanley Horticultural College for Women, Swanley, Kent.

LECTURER IN THE ENGINEERING DEPARTMENT—The Registrar, Technical College, Cheltenham, Glos.

SCIENCE MASTER or MISTRESS to be responsible for the teaching of CHEMISTRY to Higher School Certificate standard—The Headmaster, Wellingborough Grammar School, Wellingborough, Northants.

EXECUTIVE ENGINEERS for the Sierra Leone Government Public Works Department—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. E.774A).

SCIENCE IN THE NEW WORLD ORDER

THE special meeting of the Royal Society held in India on January 3 was the occasion of a message from the Prime Minister to scientific workers which should be given wide publicity. It will be remembered that, at the anniversary meeting of the Royal Society on November 30, Sir Henry Dale referred in the course of his presidential address to the visit to India of Prof. A. V. Hill, and to a proposed special meeting of the Society to be held in that country at which Prof. Hill would be able formally to admit to the Society those Indian fellows who had not hitherto been able to sign the Charter Book. The meeting took place on January 3. On that day, in the hall of St. Stephen's College, Delhi, the Indian Science Congress Association opened its annual meeting. The inaugural ceremony was preceded by a short address by Prof. Hill, who declared the great gathering to be a meeting of the Royal Society. Dr. H. J. Bhabha and Sir Shanti Bhatnagar were duly admitted and subscribed to the fellow's obligation on a sheet of parchment to be included later in the Charter Book.

With that simple ceremony, this short special meeting of the Royal Society was brought to a close; but it is safe to predict that it will long be remembered in scientific circles in India and elsewhere. H.M. the King, as Patron of the Society, was represented by His Excellency the Viceroy, who afterwards delivered an address. Prof. Hill himself reminded his audience that this was the first occasion on which the Royal Society had held a meeting outside England, and that its purpose was to convey the greetings and goodwill of the Society to the scientific workers of India. He quoted from a letter by Sir Henry Dale to the president of the Indian Science Congress Association suggesting this special meeting, in which Sir Henry said: "There is a general desire among the men of science in Britain for a more intimate collaboration with those in India who are working for the advancement of knowledge in the same fields of research", and concluding by expressing the hope that Prof. Hill's visit "will strengthen the bonds of understanding and true comradeship between Indian and British men of science".

The same notes of greeting and comradeship sounded in messages sent to Prof. Hill on the eve of his departure for India. Sir Richard Gregory, president of the British Association, the sister body of the Indian Science Congress Association, said that the "place of a country among the nations of the world to-day depends on the extent to which use is made of its resources in men and material. . . . The mission of science is the discovery of truth, to whatever consequences it may lead. The urgent duty of scientists to-day is to ensure that the message is interpreted rightly for the good of mankind." General Smuts also referred to the paramount importance of scientific research in relation to industry, agriculture, war and in other directions; and he continued, "In the great forward movement of India in our day, which is so universally acclaimed, there

is nothing more outstanding than the part her sons are taking in science and scientific research, and some of the most notable advances in physics, mathematics and the biological sciences have come from Indian workers."

Finally, Prof. Hill read the following message from the Prime Minister:

"I am very glad to have the opportunity to send through you my greetings and good wishes to Indian men of science and especially to the six Indian Fellows of the Royal Society, of which I am honoured to be myself a Fellow. It is the great tragedy of our time that the fruits of science should by a monstrous perversion have been turned on so vast a scale to evil ends. But that is no fault of science. Science has given to this generation the means of unlimited disaster or of unlimited progress. When this war is won we shall have averted disaster. There will remain the greater task of directing knowledge lastingly towards the purposes of peace and human good. In this task the scientists of the world, united by the bond of a single purpose which overrides all bounds of race and language, can play a leading and inspiring part."

There should be cause for deep satisfaction to scientific workers in these words from Mr. Churchill, because they carry a significance far beyond the occasion for which they were written. It is a truism to state that the fruits of science have been misused, and that on a vast scale. They have been misused in the past; each new discovery seems to have been matched with an evil mind ready to turn it to personal advantage at the cost of human suffering, until with the present War we have reached a climax. But, the Prime Minister goes on, "that is no fault of science". These words should be proclaimed throughout the world. Year in and year out, scientific men have been at pains to show by the written word and otherwise that scientific research is the search for truth and for the understanding of the workings of Nature, and in these columns we have continually striven to drive home their arguments. So far as men of science were concerned, we were in large measure 'preaching to the converted'; but the continued lack of appreciation of the position among those who had not had training in scientific methods justified the effort.

With the increasing utilization—intrusion some have called it—of cience in industry, transport, agriculture and practically every other phase of human activity witnessed during the twentieth century, there has been a growing tendency to put the blame for every man-made disaster, from wars downwards, on science. Both the War of 1914–18 and the present War have been notorious for the use that has been made of science for destructive purposes.

In consequence, there is still a widespread feeling among laymen that science is always and everywhere an agent of destruction, and its great gifts to mankind are overlooked or forgotten. If anyone doubts this, let him study the correspondence printed in the daily Press, or take the views of the generation now serving in the Armed Forces, on whom the building of the new world order will depend. When confronted with a modern development such as the aeroplane, it is perhaps not to be wondered at that the superficial observer may think only of the destruction that has been wrought by man's misuse of this wonderful means of transport, by means of which even the natural barriers imposed by the physical features of the earth's surface can be surmounted quickly and comfortably. The spate of propaganda that has been spilled over the world since radio-telephony became possible has made it easy to forget that broadcasting could be used equally well to bring the nations together through the exchange of cultural knowledge. 'War gases' is a common phrase, on which the comment, so well known to scientific men, that not one of the gases used or suggested for this purpose was discovered in the course of investigations directed to this end, cannot be too often repeated. Under the stress of war, little thought is given to the relief of suffering brought about by the discovery of insulin, the sulpha drugs and now penicillin, except in relation to war injuries.

The examples could be multiplied almost indefinitely, as every scientific worker knows; what he does not realize clearly enough is that the general public still requires instruction. In spite of the growth of science teaching in schools, the young people of to-day, unless they happen to be interested professionally in science, seem incapable of seeing the scientific facts they acquired at school as parts of the larger problems of modern life; their education is clearly incomplete. Here scientific workers can play a useful part; for although we cannot at present prevent man from utilizing science for destructive purposes, we can at least attempt to make him see the folly of ignoring the gifts that science offers as contributions to his happiness and welfare. Every man of science should regard himself as a prophet of the scientific era, working actively for a better understanding of the meaning of science and scientific discovery among his fellow-men.

But the Prime Minister did not stop at the exoneration of science from the blame for wars. He pointed to the future, and to "the greater task of directing knowledge lastingly towards the purposes of peace and human good". In the new world order towards which the United Nations are striving, science will be of increasing importance. To fulfil the letter and the spirit of the Atlantic Charter, great stores of knowledge about the resources of the world must be gathered in, classified and utilized with due regard to the many human factors involved. In doing this, every conceivable branch of science will be involved, and men of science of all nations, acknowledging in their work only an allegiance to the search for truth, can, in the words of the Prime Minister, "play a leading and inspiring part" in the building up of a stable civilization.

Mr. Churchill's brief message will inspire scientific men to attack the innumerable problems awaiting them during the War and afterwards with redoubled vigour and a new confidence that their work will not be in vain.

LIFE AND MENTALITY OF THE CHIMPANZEE

Chimpanzees

A Laboratory Colony. By Prof. Robert M. Yerkes. Pp. xv+321+63 plates. (New Haven, Conn.: Yale University Press; London: Oxford University Press, 1943.) 33*s*. 6*d*. net.

CHIMPANZEES are scarcely common experimental animals. In so far as they have been investigated under laboratory conditions at all, the credit is very largely due to Prof. R. M. Yerkes, until lately in charge of the Yale Laboratories of Primate Biology. It was Prof. Yerkes's insistent belief in the necessity for studying these near-human animals, and his patience in stating the case, that finally resulted in the munificent endowment by the Rockefeller Foundation of laboratories in New Haven, Connecticut, and of an anthropoid experimental station in Florida. As fast as the material facilities grew, research students were attracted. Their work over the fifteen years or so that the laboratories have been in operation forms the subject-matter of a large number of papers dealing with anthropoid psychology and physiology. Yale proved very fruitful soil for such investigations. Side by side with Prof. Yerkes's department there grew up, under Prof. J. F. Fulton, another department which is mainly concerned with the study of primate physiology, and in particular with the study of neurological mechanisms in apes and monkeys. A little later Prof. Edgar Allen joined the band, and developed in the associated department of anatomy a wide field of research into the reproductive mechanisms of Rhesus monkeys—a field which was also being covered by Dr. G. Van Wagenen in a neighbouring laboratory. These three laboratories, housed more or less under the same roof, have in the past fifteen years been the world-centre for studies of primate biology. Prof. Yerkes has only recently come to the end of his term as head of the laboratory he founded. Under the tutelage of its new director, Prof. Lashley (one of the foremost world-authorities on psycho-physiology), the future of the department is more than assured.

Prof. Yerkes has given students of primate biology a number of comprehensive works on the behaviour of apes. The best known is his reference book "The Great Apes", a compilation of all recorded observations on the lives of these animals. In his new book "Chimpanzees: a Laboratory Colony", he does not provide a general account of knowledge about chimpanzees since, as he puts it, his book is neither comprehensive nor historical; nor does he provide an epitome of studies made in the laboratories under his directorship. What he has given us is an excellently illustrated book, written primarily from personal experience and from a personal point of view, which records various facts relating to the general behaviour, social behaviour, mentality and handling of chimpanzees in captivity.

The book opens with a brief account of the natural habitat of chimpanzees and with a statement about the means by which they are captured and the uses to which they are put in captivity. Then comes a general description of their mercurial changes in attitude and behaviour and of their different temperaments and individualities. The chapter which follows is a somewhat more detailed account of social interactions between ape and ape. This is succeeded by a careful record of the growth phases and reproductive physiology of the chimpanzee and of sexual relationships. All this constitutes Part 1 of the book. Part 2 is devoted to the subject of chimpanzee mentality. Perceptual capacities, ideational behaviour, learning, memory and symbolism are each discussed in detail. Part 3 is a unique statement of the best ways to house, feed and breed the animals under laboratory conditions. The material it incorporates has never before been put together in so useful a form, and it should prove of immense value to other students of primate biology.

Two central themes which Prof. Yerkes deals with at length are the part played by the striving for dominance in the social lives of these animals, and the level of their mental evolution. Dominance is defined in terms of the dominant individual—"one who takes priority of response over its companion and is able to satisfy its needs, desires, or whims to the total or partial exclusion of another's rights". This characteristic develops in childhood and is, as Prof. Yerkes shows, a major, almost *the* major factor in the life of the mature animal. Prof. Yerkes is, however, inclined to regard the principle of dominance not so much as placing a premium on selfishness but as an insurance against individual ineffectiveness. Whether dominated animals would take the same view, or be assuaged by the occasional instances in which a dominant ape shows kindness, could only be answered by the animals themselves.

Prof. Yerkes indicates that chimpanzees can be trained to act co-operatively in a task the reward of which is, say, a piece of fruit—although in such situations the animal of "superior social status will try to encourage and direct the assistance of its subordinate companion and also do its best to monopolize the reward". In Nature almost the only truly co-operative activity of chimpanzees is mutual grooming. All this leads Prof. Yerkes to define the outstanding social characteristics of the species as "infantile social dependence, with its urge to cling; childish social attachment, with its insatiable craving for companionship; and adolescent or mature dominance, with its persistent drive for social status—a higher place in the social hierarchy". This is a very fair statement of the position.

The drive for dominance in general puts the male above the female socially. Scales of dominance, however, are not permanent. When a female is on heat and sexually desirable she becomes less subordinate—largely through what may be generally described as sexual prostitution. "The mature and sexually experienced female trades upon her ability to satisfy the sexual urge of the male. Sexual accommodation is or may be habitually exchanged for such material or personal advantages as the possession of food, desired objects, comfortable quarters, opportunity for initiative, leadership, or freedom of action". In all this the chimpanzee appears to behave in very much the same way as the baboon.

In 'mentality' and the ability to deal with experimental problems, the chimpanzee appears, however, to be superior to baboons and other monkeys, although fundamentally, as Prof. Yerkes writes, there are no "significant contrasts" in their behaviour. Essentially chimpanzees differ from monkeys in their "readiness and degree of response to training, general adaptation to experimental and other requirements, ability to learn to co-operate with each other or with Man".

The mental gulf between chimpanzee and man is, of course, much wider than that between chimpanzee and monkey. For no amount of similarity in funda-

mentals of behaviour can make up for the ape's lack of articulate speech and symbolic processes.

Prof. Yerkes's book is a great achievement and a rich contribution to the literature of the Primates. Students of the subject once again stand deeply in his debt. S. ZUCKERMAN.

THE STUDY OF MORALE

The Structure of Morale

By Dr. J. T. MacCurdy. Pp. vii+224. (Cambridge: At the University Press, 1943.) 8s. 6d. net.

IN the speaking and writing on current problems of which there is to-day such an increasing spate, discussion of values of a non-material nature frequently introduces the use of the word 'morale'. It is then employed in a loose, indefinite fashion to cover a diversity of meanings. A serious study of the whole subject by a writer of standing, qualifications and experience comes very apt to the moment.

Warren, in his "Dictionary of Psychology", allows the more general application of the term to the attitude of the group, though permitting its use in speaking of the individual, and considers that it marks the degree of confidence, perseverance in work, and adherence to ideals. The behaviour of man as a human being has long since ceased to be that of an isolated unit and to an increasing extent become that of a member of a community. According to McDougall, the positive side of the group spirit depends on the existence in the mind of each component of a clear knowledge of the group, of his place in it, and of a sentiment of devotion to it. It is important to recognize that there is an inward source of authority based on the herd instinct, leading to social cohesion and co-operation.

Dr. MacCurdy is a university lecturer on the subject of psycho-pathology; called upon in the earlier days of the War to lecture on problems of morale to selected personnel, he has wisely chosen to be practical, concrete and direct rather than theoretical and discursive. Discussion of the multiple facets of this subject has required some explanation of the common psychological urges with particular reference to the group-mind and the implications of the part played by the herd instinct in the feeling, thinking and willing of mankind. To do so he has, of course, had to cover elementary ground, to re-state the trite and to enlarge the commonplace. But Dr. MacCurdy is never dull; he always has an appositeness of remark and a convergent simplicity interesting to the informed and instructive to the ordinary man.

This very broad approach is dealt with systematically by the author. First of all he gives some attention to the place of the individual, and has taken for this purpose the nature and effects of fear. He explains the factors incident upon the individual in his dual reactions as a unit and as a member of a community, showing neatly how a man can be both frightened and brave at the same moment. Stress is rightly laid on the identification of the self with the ideal of the group, the striving urge in this direction, and the increasing pride, nay pleasure, in the acceptance of another and higher responsibility.

Perhaps the most attractive chapters in the book come in the second section, which deals with the basic principles of social life. It is to be remembered that the feelings seeking expression in the face of any given event are not the mere outcome of a momentary impulse; they represent the focus, the apex, of a wealth of interlocking, often contradictory factors stretching far back into the heredity and history of the individual. All sorts of influences—education, tradition, climate, geography, health, contacts, etc.—provide threads reaching down to and governing the immediate response. In considering all these qualities involved in the make-up of morale, Dr. MacCurdy is able to discuss the variables, such as national and religious sentiments, different scales of values, loyalties, leadership, moralities and so on. He has some very apposite remarks to make on the growth and development of national differences and tendencies in this respect, cultivated and shown consciously or not. Though he is quite ready to criticize details of our own national traits and aspirations, it is satisfying to find that he is able to come to a dispassioned judgment against the fundamentals of the German.

That confidence in the outcome which is a constituent part of morale depends very largely upon the feeling about the organization behind the effort. This again in many if not all of its details has implications of importance. In the third section of his book Dr. MacCurdy takes up the various aspects coming under the head of organization, liaison, departmentalism, caste, science and its place, democracy, dictatorships, public service: many, in short, of the difficulties inherent in the mere necessity of some sort of coordination for mutual and common ends. He is thus able to separate out and dissect in detail, but always in relation to the common factor, the multiple problems involved in our relations with our fellow-men calling for collective and accepted arrangement.

The "Structure of Morale" is a sound and competent piece of work. Written by a man of special experience and opportunities, it succeeds, though dealing largely with subjects of a strong technical flavour, in explaining with clarity and instructing with interest upon the changing values of a changing world. It is full of common sense and clear thinking. It will be read with advantage by everyone, from chief executive to railway clerk, who has any vision for things beyond the close horizon of his petty personal interests. Even these are involved, for they can never be quite disentangled from what R. L. Stevenson has so aptly called "a municipal fitness".

JOSEPH GEOGHEGAN.

FLUCTUATION IN ANIMAL POPULATIONS

Population Dynamics and Adaptive Evolution of Animals

By S. A. Sewertzoff. (In Russian.) Pp. 316. (Leningrad: Academy of Sciences U.S.S.R. Moscow, 1941.) 11 roubles.

PROBLEMS of fluctuation in numbers in animal populations are of direct interest both to those concerned with the exploitation of natural animal resources (fish, game, fur-bearing animals), and to students of evolution. Theoretical research on these problems is visualized by the author mainly as investigation of facts illustrating the Darwinian theory of the struggle for existence. According to him the overwhelming importance of the struggle for existence is overlooked by the majority of theoretical biologists, and this accounts for the spread of such idealistic theories as hologenesis, Lamarckism, nomo-

genesis, etc., while a tendency to ignore Darwinian ideas is characteristic of 'bourgeois science'. Such a view of Western biology may cause some surprise, as it is scarcely justified by the modern trends in its development, which appear to have remained largely unknown to the author. In fact, when discussing evolutionary theories later in the book, he directs his polemics against O. Abel and Beurlen, neither of whom can be called very modern, or typical of Western science.

The first part of the book is introductory and contains a review, which is not very up to date, of the basic principles of population dynamics, such as the curves of population growth; specific constants of reproductive ability; longevity curves; etc. The second part, occupying nearly half the book, is the most interesting one, as it comprises detailed analyses of fluctuations observed in populations of various game birds and animals, mainly in the Gatchina game reserve, where exact records of the game bred and shot have been kept for twenty-five years (1884–1909). Other data are those on the dynamics of the bison and other game in the Bialowiezh forest in the period 1809–1916; of the seal population in the Pribyloff and the Komandor islands in 1912–1932; of wolves in Central Russia in 1917–1924; of squirrels in 1891–1908; of hares in Russia in 1825–1898; of voles and other rodents; etc.

The third part is closely linked with the second, as it is given to the discussion of the theories of population dynamics. The curves of increase in populations and of mortality of every species are, according to the author, as characteristic of the species as its morphology or physiology. Fluctuations in populations are due to a gradual increase, regulated by the action of predators, which, however, can only influence the length of the cycle but are never able to overtake the increase in the population of the prey, and thus to cause the collapse of a cycle. The collapse is always sudden and is usually caused by an epizooty, in the spread of which the density of the population is a most important factor; in less frequent cases, the collapse may be due to a climatic catastrophe. This sudden reduction in the prey population causes a reduction in the number of predators due to lack of food, and this makes a new increase of the prey possible. The author's theory, therefore, only partly coincides with those of Volterra and of Elton; a possible direct correlation between population cycles and climatic cycles is rejected by the author, practically without argument.

The fourth part, entitled "Ecology and the Evolution Theory", begins with an attempt to analyse the facts of population dynamics against the background of the Darwinian struggle for existence, and the well-known conceptions of life-form, ecological niche, biotic potential, etc., are discussed. This leads the author to consider the evolution of species in their relations to environment, but instead of analysing this problem with concrete ecological data, he transfers the discussion to the question of adaptations, not of individual species, but of large phyletic groups, and many pages are devoted to Osborn's and A. N. Sewertzoff's theories of adaptive radiation and evolution. This chapter is followed by one dealing with the problem of longevity and mortality in different groups, and a conclusion is reached that long-lived species are less fertile than the short-lived ones, but their mortality is also lower and their numbers less subject to fluctuations. This interrelation permitted the author to develop a mathematical formula showing that the fertility of a species is a logarithmic function of its longevity. The formula has enabled him to construct a series of species of mammals, birds, reptiles and fishes, which make it possible to arrive at definite conclusions with regard to the relative intensity of the struggle for existence in these classes. A special chapter is devoted to checking the general conclusions on mammals; the evolutionary history of the class is recapitulated and found in harmony with the author's theories. In the concluding chapter the author rather suddenly reverts to the practical aspect of the subject and supplies a somewhat sketchy account of the influence of man on populations of wild animals, and also points out the importance of a knowledge of the laws of population dynamics for those concerned in fisheries, game-keeping, etc.

The book leaves a very mixed impression. Its purely ecological chapters are most interesting because of the author's dynamic approach and his masterly dialectical analysis of a mass of valuable data from Russian sources, but his attempt to justify the life-long morphogenetic and phylogenetic work of his brilliant father, A. N. Sewertzoff, by its somewhat remote connexion with purely practical problems, appears scarcely necessary. Unusual features of the book are an almost complete lack of reference to the genetic aspect of population dynamics and of evolution; and repeated protestations of the Darwinian orthodoxy of the author's views. The bibliography is rich in Russian references of great value to ecologists and population students, but there are no references to publications in other languages after 1937. B. P. UVAROV.

AN UNSCIENTIFIC HISTORY OF SCIENTIFIC THOUGHT

From Copernicus to Einstein

By Hans Reichenbach. Translated by Ralph B. Winn. Pp. 123. (New York: Philosophical Library, Inc., 1942.) 2 dollars.

ON the jacket of this book the publisher states that "this is a simple but scientific history of ideas and discoveries that have led to the formulation of the theory of relativity. . . . The wealth of ideas contained in it tend to make it a distinguished contribution to scientific thought. It is well illustrated with charts and diagrams. The book is especially intended for the scientific as well as amateur astronomer and physicist." The reader will soon discover that these statements are quite unjustified; that the book abounds with erroneous statements, that the historical perspective is often wrong, that the wealth of ideas is conspicuous by its absence and that the translation is so bad that it is sometimes impossible to understand what is meant. The illustrations consist of eleven crude diagrams.

In the first few pages, for example, views are ascribed to Ptolemy that are much earlier in point of time. The author states that the "De Revolutionibus" of Copernicus appeared in 1546, after the death of Copernicus, and that Copernicus read the proofs on his death-bed; Copernicus never saw the proofs, and the book appeared in 1543, a copy reaching him a few days before his death. It is not correct that "the Copernican theory offers a very exact calculation of the apparent movements of the planets", nor that this was one of the reasons that led to its accept-

ance: Copernicus himself said that he would be delighted if he could make his theory agree with observation within 10′. It is not true that Copernicus was able to break with an old belief "only because he had at his disposal a considerable amount of accumulated scientific thought and scientific data". The statement that with the astronomical instruments of to-day angles can be measured "within one hundredth of a second of the arc" shows a lack of appreciation of the errors of observation. It is not correct to state that Copernicus "was of the opinion that the solar system virtually exhausted the space of the Universe"; Copernicus asserted that the stars were at an immense distance, but left the question whether the world was infinite and without bounds for philosophers to discuss.

The account of the work of Tycho Brahe and Kepler is misleading. Kepler was able to prove that the orbits of the planets are elliptical because Tycho had not restricted his observations of the planets, as his predecessors had done, mainly to the times near opposition, but had observed them right round the heavens; this is not mentioned. The statement that Kepler "discovered through mere measurement also other laws of planetary motion, called after him 'the Kepler's laws'" gives a poor idea of Kepler's long and laborious investigations. It is not correct that to Copernicus and Kepler the stars "were tiny dots in the sphere of heavenly matter". Giordano Bruno was not the first person to assert that the firmament was infinite; this was stated by Thomas Digges, from whom Bruno probably adopted the conception. Galileo did not make the first serviceable telescope, and he did not see Venus as a sickle-like shape, but as a crescent. He did not designate the major satellites of Jupiter as the "medizeic planets". To state that he discovered that "all bodies fall equally fast" is inaccurate. The statement that "fate allotted to the English physicist Isaac Newton an outstanding role in the history of the natural sciences of the described period" is a poor tribute to the genius of Newton.

A few specimens of the translation will suffice to show its crudeness. "Electrical waves are advancing fields which should not be regarded as bound to a material medium. They are waves in which electricity continually alternates between positive and negative. Yet they are not dependent on the ups and downs of small material particles, but move quite independently through space. They thus have qualities found by the science of optics in the slow course of experimentation with light." "Such reflections were entertained with regard to ether and in connection with astronomical relations. As light traverses the world's space, ether must fill it like a great mass of water in which planets float like isles. Insofar as planets move around the sun, they must be characterised by a different state of motion from that of ether. Thus one comes to the assumption that the velocity of light, as measured on a planet like the Earth, must vary with direction, simply because ether is understood as a substratum of light waves and only with regard to it can the velocity of light receive its natural value". "What is maintained by Einstein with regard to light goes, therefore, for all electrical waves of which light is but a representative. But according to our knowledge of the internal structure of all substances, there are basically only two ways of transferring power from body to body; gravitation and the electrical wave. Every other manifestation of force is composed of them. If they both move with the velocity of light, as Einstein contends, then a slowing up may occur within the atoms of the body, when the power runs in a zig-zag course; but it can never be accelerated. Einstein's law of the limit character of the light-velocity means thus nothing other than a formulation of the fact that light represents one original form of the transfer of action, the other representing an equal speed limit".

The quotations will suffice to show that the book cannot be recommended. H. SPENCER JONES.

LANGUAGE IN THE MAKING

The Gift of Tongues

By Prof. Margaret Schlauch. Pp. ix+342. (London: George Allen and Unwin, Ltd., 1943.) 12*s*. 6*d*. net.

MARGARET SCHLAUCH is a professor of English at New York University and teaches Chaucer, medieval literature and language. In the "Gift of Tongues", however, she has directed attention to the study of linguistics for the layman. The matter is so varied in style and content that it is difficult to comment on the book as a whole. Generally, it is well written and reads easily; much of the reader's enjoyment comes from a liberal sprinkling of sly humour which never obtrudes. Among the many subjects dealt with by Prof. Schlauch are the early origins of language, the use of names in magic, the evolution of written language through pictographs, ideographs and hieroglyphs to fixed alphabets and the study of semantics.

The possibilities of basic English as an international language is discussed in a chapter dealing with the history of the English language. A section on grammar gives a brief outline of the principles of sentence construction in the Aryan family of languages and then proceeds to show that our own system is, after all, but one system, based largely on Latin. An interesting account of the emotive qualities of words leads on naturally to the use and need of linguistic knowledge in studying some modern poets like James Joyce, Gerard Manley Hopkins, Gertrude Stein, Hart Crane and others whose works are reputed to be 'difficult' because of their deliberate use of verbal distortions, puns, overtones and double shades of meaning. The work of modern poets in using words in their original meanings and free from the impediments which have obscured their original meanings is also considered.

Men of science, as well as Mrs. Malaprop and other *arrivistes* in language, would find much to interest them in the chapter concerned with the social aspects of language and its significance in class, superstition, and politics. In this connexion it is easy enough to agree with Prof. Schlauch that "linguists will gain and give most when they unite the traditional scrupulous regard for scientific method with vivid and realistic awareness of social milieu and its challenging problems. To do this they will have to receive help from, as well as give it to, other disciplines such as sociology and psychology", as well as her further remark that "no part of language study offers better occasion for scientific collaboration than the investigation of meanings against a social back-ground".

The book is thoroughly annotated and contains a well-ordered and lengthy bibliography. The series of questions and illustrations at the end would be useful as diversion for the layman and exercise for the student. T. H. HAWKINS.

CHEMICAL ASPECTS OF THE VISUAL PROCESS

By DR. R. A. MORTON
University of Liverpool

THE chemistry of photo-reception remains obscure in spite of a vast literature, particularly rich in biophysical data; indeed it is doubtful whether on the chemical side present theories are more than the merest scaffolding. Recent statements by well-known workers display a confidence about the nature of visual purple (rhodopsin) which it is not easy to share. It is said to be "safe to assume that visual purple is a conjugated carotenoid-protein" (Hecht[1]); rhodopsin "is a conjugated protein with a carotenoid prosthetic group called retinene; it is estimated that one molecule contains 10 prosthetic groups and that each such group contains one molecule of vitamin A" (Mitchell[2]). "Rhodopsin is a rose-coloured carotenoid-protein, in aqueous solution its absorption spectrum consists of a single broad band maximal at 500 mμ. In light it bleaches in a succession of photochemical and thermal reactions to orange and yellow products, liberating *in the process* the carotenoid retinene" (Wald[3]). "No doubt, therefore, the A vitamins are of importance for the formation *of the chromophoric group* of the visual purple molecule, even though it may not be possible at present to describe the nature of this relationship" (Granit[4]).

The existence of retinene was revealed by the work of Wald. It is defined by him as the substance which gives rise to a blue-green colour with chloroformic antimony trichloride, characterized by a sharp absorption band at 664 mμ. Retinene disappears when intact dark-adapted retinas are illuminated and is replaced by vitamin A ($\lambda_{max.}$ 620 mμ in the antimony trichloride colour test). The cycle:

$$\begin{tikzcd} & \text{Rhodopsin} \arrow[dr, "\text{light}"] & \\ \text{vitamin A} + \text{protein} \arrow[ur, "2"] & & \text{retinene}_1 + \text{protein} \arrow[ul, "1"'] \arrow[ll] \end{tikzcd}$$

plausibly summarizes the role of vitamin A in preventing abnormally slow adaptation to dim light (scotopic vision). The discovery of vitamin A_2, and of the pigment porphyropsin in the retinas of freshwater fishes, led to the idea of a parallel cycle:

$$\begin{tikzcd} & \text{Porphyropsin } (\lambda_{max.}\ 532\ m\mu) \arrow[dr, "\text{light}"] & \\ \text{vitamin } A_2 + \text{protein} \arrow[ur, "2"] & & \text{retinene}_2 + \text{protein} \arrow[ul, "1"'] \arrow[ll] \end{tikzcd}$$

With the antimony trichloride reagent, vitamin A_2 gives a colour with $\lambda_{max.}$693 mμ and retinene$_2$ a colour with its maximum absorption at 706 mμ. Direct absorption spectra of solutions containing retinene$_1$ and retinene$_2$ reveal maxima at 387 and 405 mμ respectively, which are plausibly but not conclusively attributed to these substances.

Wald's observations created an interesting and promising situation, but as has happened before in visual purple research, progress appears to have halted. The reason is probably a lack of working hypotheses. No suggestion has been hazarded as to the chemical relationship between the vitamins A and the retinenes. No mechanism has been advanced to account for the conversion of vitamin A ($\lambda_{max.}$ 325 mμ, practically colourless in dilute solution) to the rose-coloured visual purple. No explanation is available of the fact that in studying the photo-decomposition of visual purple *solutions*, vitamin A could not be found at any stage (Krause and Sidwell[5], Wald[6]).

Vitamin A, a fat-soluble alcohol $C_{20}H_{29}OH$, is not known to form *p*H-sensitive derivatives: yet visual purple undergoes photo-decomposition to yield a succession of products, all of which are *p*H-sensitive:

$$\underset{(\lambda_{max.}\ 500\ m\mu)}{\text{visual purple}} \rightarrow \underset{(\lambda_{max.}\ 470\ m\mu)}{\text{transient orange}} \rightarrow \underset{(\lambda_{max.}\ 445\ m\mu)}{\text{indicator yellow}} \rightarrow \text{colourless products}$$

(Lythgoe and Quilliam[7], Wald[6]).

According to Wald, a succession of changes occurs, and though the spectrum of rhodopsin itself is unaffected by *p*H changes, the spectra of all stages of bleaching are highly *p*H-labile. "Rhodopsin apparently does not possess an acidic or basic grouping in close association with its chromophore, but such a grouping is exposed as a first result of irradiation (cf. Lythgoe). The effects of *p*H change on the absorption spectra of bleached products are in some cases large and peculiar, probably because they involve complicated mixtures of pigments."

It has been shown that the quantum efficiency of the primary photochemical process in the decomposition of visual purple is about unity and the molar extinction coefficient (at 506 mμ) is $2{\cdot}3 \times 10^4$ (Dartnell, Goodeve and Lythgoe[8]).

In itself this is scarcely consistent with a 'carotenoid' prosthetic group, since $\varepsilon_{max.}$ is 5×10^4 for vitamin A and 1×10^5 for β-carotene.

Vitamin A deficiency not only delays dark adaptation in scotopic (rod) vision but also very definitely affects photopic (cone) vision. The duplicity theory is firmly established and vitamin A is concerned in both mechanisms. Nothing, outside the problems of vision, is known about vitamin A or its derivatives to indicate abnormal photo-sensitivity, and the idea that the *chromophoric group* of visual purple is retinene or any other vitamin A derivative does not compel assent. The chromophoric or prosthetic group may well be entirely different; it may be an unknown or a known substance.

In fact, it has already been suggested that riboflavin (or a related compound), which is known to occur in relatively large amount in the eye, may "take part in the visual processes by means of its photo-chemical properties such as fluorescence and light-sensitivity" (Adler and v. Euler[9]). The photochemistry of riboflavin, of its phosphate and of the yellow enzymes is complex; there is a sequence of changes, *p*H-sensitive and oxygen-sensitive products being formed. "If the flavin of the retina is associated with colour vision, it is thought probable that the change of the flavin to a primary photo-body furnishes the nerve stimulation. The irreversible change of the photo-body to deutero-riboflavin, which would be a loss of valuable flavin is prevented by O_2 in the retina" (Theorell[10]). That flavin is in some way connected with the visual process seems clear from Pock-Steen's report that twilight blindness in 'leiodystonia' and sprue was alleviated by riboflavin but not by vitamin A. No attempt seems to have been made to reconcile the 'flavin' and 'vitamin A' hypotheses.

Of the possible changes which vitamin A (delivered to the eye via the blood stream as free alcohol $C_{19}H_{27}.CH_2OH$) could undergo, the first to be considered is clearly:

$$C_{19}H_{27}.CH_2OH \xrightarrow{-2H} C_{19}H_{27}.CHO.$$

This change is physiologically plausible. Unfortunately, vitamin A aldehyde has not been prepared, although Heilbron and his colleagues[11] tried to make it from the alcohol by the use of Oppenauer's method. Instead, they obtained $C_{23}H_{32}O$, probably $C_{19}H_{27}CH{=}CH.COCH_3$ ($\lambda_{max.}$ 401 mμ, antimony trichloride colour test 646 mμ) and $C_{19}H_{25}CHO$ (one additional double bond in the terminal six-membered ring). The aldehyde showed $\lambda_{max.}$ 401 mμ and a colour test $\lambda_{max.}$ 740 mμ. The reduction product $C_{19}H_{25}.CH_2OH$ gave $\lambda_{max.}$ 359 mμ, antimony trichloride colour test, 728 mμ. In attempting to judge whether the retinenes resemble the hypothetical vitamin A or A_2 aldehydes, it is necessary to recall a peculiarity of the colour tests. Vitamin A with antimony trichloride shows $\lambda_{max.}$ 620 mμ with a pronounced inflexion near 583 mμ. Colour-test inhibitors (for example, 7-methyl indole) suppress the 620 mμ band, and the 583 mμ maximum is revealed. Similarly, the vitamin A_2 colour test shows absorption maxima at 693 mμ and 650 mμ under certain conditions. The ease with which vitamins A and A_2 can be made to exhibit either of two maxima in the colour test at once raises the question whether the observed maxima for retinene$_1$ and retinene$_2$ are respectively comparable with the longer or shorter wave-length maxima :

	$\lambda_{max.}$ mμ	Antimony trichloride colour test maxima	
Vitamin A_1	325	620 and 583 mμ	
Vitamin A_2	350	693 and 650	
Retinene$_1$	387		664
Retinene$_2$	405	706	
$C_{19}H_{27}CH{=}CH.COCH_3$	401		646
$C_{19}H_{25}CHO$	401	740	
$C_{19}H_{25}CH_2OH$	359	728	

Two points emerge : first, the importance of preparing vitamin A aldehyde ; and second, the need for a full study of the colour test. The ultra-violet maximum for the aldehyde might be expected to fall near 360–370 mμ.

I have observed a 664 mμ chromogen (*a*) in extracts from *aged* processed human blood plasma and (*b*) in a fraction from bovine serum. In both cases the chromogen was probably an artefact. It has also been obtained by the oxidation of pure vitamin A but much contaminated with other products. Optimum conditions are elusive, but three workers (T. W. Goodwin, R. H. Creed and myself) have repeatedly seen the band, using CrO_3 or $KMnO_4$. Pure vitamin A (0·05 per cent) in cyclohexane rapidly decolorizes aqueous $KMnO_4$ (0·25 per cent in amounts up to 30 per cent of the volume of vitamin solution) on shaking in the cold in the presence of a little 5 per cent H_2SO_4. The supernatant cyclohexane solution is pipeted off and tested with the $SbCl_3$ reagent. With small amounts of permanganate the blue colour is greatly weakened; with increasing amounts the colour changes through purple to blood-red. Using sufficient of the cyclohexane solution, colour-test maxima at 664, 615 and 565 mμ can be seen, with a further band at 642 mμ appearing slowly. The first band is not always easy to obtain, but its detection fits into the pattern of facts. Acknowledgment is made to Prof. T. B. Davie and to Drs. F. H. Carr and T. H. Mead for material and to Prof. T. P. Hilditch for suggestions.

The possibility that vitamin A might be dehydrogenated to the aldehyde under physiological conditions is not unreasonable in the light of what is known of such enzyme systems as those involving di- or tri-phosphopyridine-nucleotides, but it affords of itself no hint as to the origin of colour in rhodopsin. On the other hand, it possibly fits the failure to find vitamin A in the decomposition products of visual purple solutions. Suppose that in the intact retina, vitamin A in equilibrium with its aldehyde occurs as a part of, or in proximity to, visual purple. The process of extracting pigment or hardening the retina would 'freeze' the equilibrium. In the dark-adapted retina this might well be very much on the side of the aldehyde, and in the absence of functioning enzyme systems the aldehyde might be expected to decompose slowly but irreversibly by oxidation.

Now the "main chemical alteration which occurs in the retinal tissues on exposure to light is a general tendency to become acid. . . . The degree of acidity varies directly with the intensity and duration of the exposure to light and is greatest with yellow-green light" (Duke-Elder[12]). Irradiation involves the formation of phosphoric acid which disappears in the dark (Olmsted[13]). The identification of phosphoric acid as a part of the photochemically initiated sequence of changes is a further complication to the 'carotenoid-protein' hypothesis.

If there are objections to ascribing the visual purple absorption curve to a 'carotenoid', there are also difficulties in the suggestion that the chromophore is a flavin. The various yellow enzymes (containing alloxazine-nucleotides) all show maxima near 465, 380 and 275 mμ, but the visible absorption is too low both in respect of $\lambda_{max.}$ and $\varepsilon_{max.}$ to fit the prosthetic group of visual purple.

Absorption maxima of yellow enzymes.

Cytochrome reductase	275, 385, 455 mμ
'Old' yellow enzyme	275, 380, 465
'New' yellow enzyme	275, 377, 455

(Haas, Horecker and Hogness[14]). There is, however, no doubt that a marked inflexion occurs near 490–495 mμ, corresponding with a somewhat masked absorption band (cf. Theorell and Haas[15]).

Early in the work on riboflavin it was observed that reduction in 10 per cent hydrochloric acid gave an intense red intermediate phase ($\lambda_{max.}$ 490 mμ) also recorded for alloxazines like lumiflavin (Kuhn and Wagner-Jauregg[16]; Stern and Holiday[17]). This semiquinone formation has also been shown to occur under much more physiological conditions when yellow enzyme is reduced in the presence of a large excess of tri-phosphopyridine-nucleotide (Haas[18]). The red ferment is thus probably a flavin-pyridine-nucleotide, both prosthetic groups being bound to protein.

	$\lambda\lambda_{max.}$	
Yellow enzyme	465	380 mμ
Red phase	475	360

This red ferment is the closest physiologically plausible analogue of visual purple which is so far known. It requires, however, a reducing agent which shall effect an easily reversible partial reduction at the alloxazine ring. The 'flavin' and 'carotenoid' functions can be married by attributing this reduction to vitamin A aldehyde. On this basis the aldehyde, accumulating sluggishly through the action of, for example, tri-phosphopyridine-nucleotide on vitamin A, conditions the speed of visual purple regeneration. The primary photochemical process will not be a reversal, but a partial direct oxidation to yellow enzyme, and vitamin A aldehyde will not be affected. Hence retinene could be obtained from dark-adapted retinas, and in visual purple *solutions* would be oxidized away. The alloxazine-nucleotide oxidation-

reduction system, moreover, affords a rational basis for electron liberation.

Any adequate working hypothesis for the visual process requires *stages* in the oxidation-reduction system. According to the work of Kuhn and Ströbele[19], such stages are demonstrable with araboflavin :

		Oxygen uptake in regenerating 1 mol. flavin
Flavin	yellow	0
Verdoflavin	bronze-green	0·25
Chloroflavin	grass-green	0·50
Rhodoflavin	carmine-red	0·75
Leucoflavin	colourless	1·0

In the case of "photo-hepato-flavin", Stern and Holiday record :

		$\lambda\lambda_{max.}$
Holoquinone	neutral	364, 440 mμ
,,	in 0·2 *N* HCl	267, 385 mμ
,,	in 0·2 *N* NaOH	263, 352, 442 mμ
Semi-quinone	in 0·2 *N* HCl	358, 490 mμ

It is conceivable that the 387 mμ maximum recorded by Wald for retinene is really due to a flavin concomitant and not to the 664 mμ chromogen. It is a curious fact that the lens emits a pale greenish-yellow fluorescence, the most effective spectral region for its production being 370–390 mμ, maximum 385 mμ (Hoffmann, quoted by Duke-Elder[20]). I have obtained from horse lenses a chloroform-soluble material absorbing in this region and giving a strong sky-blue fluorescence (possibly due to dimethylalloxazine).

Vitamin A aldehyde could be replaced by vitamin A_2 aldehyde without fundamentally affecting the 'flavin' mechanism for scotopic vision. It could likewise function in photopic vision. Here it is not irrelevant that the optical properties of planar molecules are known to be susceptible to change with dimer and polymer formation, and with molecular orientation both with respect to surfaces and molecular axes.

To summarize this discussion, an attempt has been made (1) to account for the evidence that poor scotopic vision may follow from avitaminosis-A *or* -B_2 ; (2) to suggest a mechanism for the intervention of vitamin A (or A_2 in freshwater fishes) ; (3) to explain why vitamin A is not obtainable from visual purple solutions ; and (4) to devise a mechanism which allows vitamin A to participate, albeit indirectly, in both photopic and scotopic vision, without leaving the photochemical problem in mid-air.

The whole range of trustworthy data on visual processes and perhaps even of bioluminescence will need to be fitted into an acceptable theory. It is of small consequence if the suggestions now made turn out to be inadequate as new facts are gathered. The important thing at this stage is that the chemical aspects of the problem should be focused more sharply, and the difficulties faced.

STATISTICS IN SEDIMENTARY PETROLOGY

By DR. P. ALLEN
University of Reading

RECENT publications show that at long last there is a flood-movement in British geological research towards the accumulation of increasingly precise quantitative data. The transition from the qualitative phase, painfully slow at first, has lately been accelerated in most branches of the science. This limited progress is especially marked in sedimentary petrology, where Fleet, Butterfield, Smithson and Walder have raised a banner which all must surely follow.

Without a doubt this vigorous movement marks only a beginning. Already some of its protagonists, wallowing in a mire of seemingly endless figures, are beginning to question the wisdom, and indeed the reliability, of their laborious endeavours. Attempts at extrication by crude mathematical methods (concerning the reduction and not the reliability of data) have met with little success. Other petrographers, less desirous of reaching immediate conclusions, are content merely to amass information of unqualified precision in the hope that one day it may prove useful.

All the present difficulties and discrepancies have one common underlying cause. They are due entirely to the widespread inability of geologists first to recognize, and secondly to deal with, the various types of population commonly encountered in petrological research. No matter if these populations are finite or infinite, and irrespective of which sedimentary variates they concern, their behaviour and its repercussions remain uninvestigated and almost completely ignored. Yet, to quote the most fundamental example, all petrological work, even that concerned with the smallest finite populations, relies on sampling for its practicability. Consequently, though the distinction between some of the statistics actually used, and the parameters estimated, may often be recognized, no allowance is ever made for it—the penumbræ of error darkening our petrological morass are left well alone ! Yet it is idle merely to record the useless fact that zircon reaches a mean size of "50 μ" in a certain locality ; statement of the statistic in conjunction with its (qualified) standard error—as "50 μ ± 3 μ"—conveys information of considerable geological value.

In consequence of the shortcomings outlined above, interpretations drawn from quantitative petrographical data usually either do not justify the laborious methods used, or (especially when 'conclusive') are largely unwarranted. The former situation involves waste of data and both involve waste of time. Indeed, I know of no geological work (published in Britain) that contains one conclusion stated as an honest mathematical probability. I am also unaware of any paper devoted mainly to quantitative information which is enlightened by a really comprehensive account of the sampling and analytical techniques employed. Truly, appraisal by the sceptic is normally quite impossible. Consistently with this state of affairs, investigations planned to achieve desired degrees of precision—indeed degrees of precision themselves—are practically unknown in British geology. The present difficulties are all the more surprising when we consider that the mathematical techniques necessary for their removal have existed

for some time. One can only conclude that for three decades most geologists have worked in complete oblivion of the progress of statistical science.

During the past five years, much work in the Department of Geology at the University of Reading has been devoted to the application of statistical methods to geological problems, especially those of a petrological and stratigraphical nature. In the sphere of sedimentary petrology the mathematical techniques have already more than justified their adoption.

Selection of Fields of Study

Statistical control exerts its first influence in the selection of fields of study. The preferable fields are those which permit detailed investigation of (1) the areal petrographical characters of widespread but thin horizons (less than 6 in. thick), and (2) the vertical petrographical successions in single localities. By the first approach an attempt is made to treat certain selected geological 'moments' separately throughout their accessible extents, and so to elucidate the *spatial* distributions of their petrographical characters. By the second, the distributions *in time* of petrographical characters are studied at selected points. In such a manner the invalidating effects of the two types of distribution upon one another may be minimized each in turn. Unfortunately, the nature and number of actual and potential exposures very often leave the sedimentary petrologist no choice but to concentrate largely upon one or other of the two viewpoints. When quarries and other sites are normally small but very numerous (as in the Wealden rocks of south-east England), horizonal studies often yield the more valuable results; when they are extensive but few (as in the Tertiaries of the Isle of Wight, now being studied by my colleague Miss P. S. Walder) investigation of the petrographical sequence in time frequently appears to be the more promising. I recently completed an areal study of the Top Ashdown Pebble Bed[1] in the Weald of Kent, Surrey and Sussex, using an arbitrary 2-in. horizon situated 4 in. down in the underlying sandstone as 'control'. Since the efficacy of statistical methods has been most fully tried out on this sediment, particular reference thereto is made in the present outline.

If a horizonal study has been decided upon, the petrologist should next ensure that the sampling on which it is to be based will be as nearly random as possible. The distribution of satisfactory exposures usually limits him in this respect, because, being controlled by factors other than chance, it is not necessarily a random one. Secondary sampling from them at random is seldom possible either, for the exposures at any one widespread horizon less than 6 in. thick are usually all too few at the start. The sandpits and openable sites at the Top Ashdown Pebble Bed horizon were apparently distributed according to factors quite unrelated to the petrographical characters of the bed. The risks inherent to an assumption of randomness, being therefore considered minimal, were ignored, and attention was merely focused upon ensuring random sampling within the sites located.

Choice of Statistics

Preliminary analysis of a few field samples (by the usual methods of gravity separation, and counting of *entire* residues) indicates the range of statistical values likely to be necessary for the subsequent sample and horizonal characterizations. In general, the constituents of sediments are found to be most easily dealt with through separate consideration of two or three fractions, namely, (1) the allogenic pebble suite (when present), (2) the allogenic light and heavy grain suites, and (3) the authigenic light and heavy suites. The minimum quantitative requirement is that in every field sample each of these five suites shall be fully characterized by statistics relating to frequency, abrasion, grade size and sorting. The frequencies (expressed as percentages) of all pebble and mineral grain species, varieties and other distinctive types, should be determined, together with their 'errors'. The degrees of abrasion are best expressed as the percentages of euhedral, subangular, angular and rounded individuals (suitably defined), average size as their arithmetic mean sizes (based on measurements of intermediate axes), and degrees of statistical sorting as the coefficients of variation derived from the data yielding their means. Calculation of errors is of course necessary in all cases.

During the study of the Top Ashdown Pebble Bed, the determination of the grade sizes and degrees of sorting of all the species, varieties, etc., in every subsample was found to be too time-consuming. This difficulty was overcome in the case of the allogenic heavy suite by using the values pertaining to zircon (probably the most stable mineral) as indexes typifying the whole suite. The validity of the method was confirmed by replicate analysis and by detailed comparisons with other species. The allogenic heavy grain suite of each Ashdown field sample was thus finally characterized at least by (1) complete frequency analysis, (2) the 'zircon abrasion index' (equals per cent of euhedra among the zircons), (3) the 'zircon size index' (equals the mean size of zircon), and (4) the 'zircon statistical sorting index' (equals the coefficient of variation of the zircon grain-size distribution).

Estimation of Minimum Subsample Size and Standard Errors

The field sampling and characterization designs having been settled, it is necessary to estimate the minimum number of pebbles or grains in the subsamples pertaining to each suite which will be necessary to achieve sufficient accuracy for studying the variations anticipated in the various populations of the sediment. Analysis of a few subsamples of arbitrary sizes from widely different sedimentary grades usually suffices for a provisional estimate. In the case of the Top Ashdown Pebble Bed, the subsample sizes were standardized at greater than 200 for pebbles and greater than 1,000 for grains.

In order to establish the degrees of significance of the chosen statistics and to recognize when significant differences exist between them (within the aims of the investigation), the petrologist must be able to estimate their associated 'errors'. Because these (best expressed in the form of standard errors) necessarily always embody components due to random sampling (SE_r) and experimental treatment (SE_e) they may be termed 'total standard errors'. Their magnitude will vary with the project and the consequent unit of comparison—normally either the subsample, the 'patch' or the 'locality'.

1. *Standard Errors of the Subsample* (SE_s). During the preliminary work it is convenient first to investigate the total standard errors (SE_s) of statistics referring to the adopted subsample alone. Values for these, in terms of their component sampling errors, may be obtained from series of replicate analyses of homogenized material drawn at random from the known grade-size range of the sediment. For pur-

poses of improvements in laboratory technique, SE_s may also be calculated for each species from the data. In the case of frequencies, significant differences between the total and the sampling errors within series are best tested by χ^2, using Brandt and Snedecor's formula[2]. Graphed against frequency, the values (k_s) of the ratio SE_s/SE_r determined for each species may be used in the subsequent assay as a basis for estimating the total errors from the sampling errors of single values. In this way the otherwise inevitable replication of each sample in the main investigation is obviated. SE_s is most necessary for use in the tests of significance involved during the study (by concentrated sampling) of local small-scale petrographical variation, or 'patchiness'.

2. *Standard Errors of Patchiness* (SE_p). Combined with the thin sampling normally forced upon petrologists, SE_s is not, unfortunately, necessarily large enough to deal with the establishment of more widespread changes, such as the recognition of minor petrographic 'regions'. Estimation of a sufficiently comprehensive error, the 'standard error of patchiness' (SE_p), allowing for small-scale variation within the sediment, may be conducted in the same general way as that of SE_s, but using instead the ratios (k_p) derived from random series of replicate samples of *unmodified* material, the latter being taken at random from small horizonal areas of constant size. For the Top Ashdown Pebble Bed these areas were fixed at ½ sq. ft.

3. *Standard Errors of Locality* (SE_l). When horizonal sampling is thin, and broad petrographic regions are to be established, the unit of comparison strictly becomes the locality, and an error even more comprehensive than SE_p is needed. One such, the 'standard error of locality' (SE_l), may be estimated as before from its component sampling error by means of specific factors (k_l) obtained from preliminary replicate sampling within 'localities'. During the study of the Top Ashdown Pebble Bed, a 'locality' was defined as a quarry of a certain size. Unexpectedly, however, analysis of variance showed that none of the values obtained for k_l significantly exceeded the corresponding k_p's, and SE_l was consequently taken as approximately equal to SE_p.

Manipulation of Standard Errors

The three standard errors may be manipulated during the subsequent work in the usual way, the particular error used and the level of significance chosen varying with the aims in view and the sampling concentrations achieved. The assumption that the distributions of the variates concerned are normal must necessarily be provisional until they are more extensively investigated.

Much arithmetical labour may be avoided in the large numbers of frequency comparisons afterwards carried out, by preparing beforehand curves of significant differences based on the various k-factors and the chosen level of significance. The level of significance adopted during the Ashdown work was $P < 0{\cdot}05$, and since all grain counts either equalled or exceeded 1,000 individuals, a frequency p_1 per cent of a mineral was considered to be significantly different from that (p_2 per cent) in another sample only when

$$p_2 > \frac{50(5p_1+k^2)+k\sqrt{2500k^2+100(k^2+500)p_1-(k^2+500)p_1^2}}{250+k^2},$$

where k was the value of k_s, k_p or k_l appropriate to the mean of p_1 and p_2. Curves were therefore prepared for the above relation as an identity (graphing p_2 against p_1) when $k = 1, 1{\cdot}5, 2, 2{\cdot}5, \ldots, 6{\cdot}5, 7$. From these, the status of a large majority of differences could be read off at sight.

The pebble counts were treated in the same general way.

Mapping of Statistics

The kinds of statistic relating to the several species, varieties, etc., obtained during the main investigation, are best plotted on to separate maps as they are obtained, and their frequency distributions finally inserted thereon. The latter may be examined by moment-analysis.

During the insertion of 'contours' designed to emphasize the main trends of change and similarity, rigid statistical control is vitally necessary if they are to have any real meaning. By far the best scheme is to make the contour intervals equivalent to minimum significant differences; for example, for $P = 0{\cdot}05$ when the total counts always exceed the intended minimum size.

When the collection of data concerning the horizon is completed, statistical reduction and analysis of variation become guides to interpretation rather than policemen to methods. The analysis and inter-horizonal comparison of correlations between variates, neatly carried out in terms of the correlation coefficient (r), is illustrative in this respect. Several significant correlations (up to $+ 0{\cdot}71 \pm 0{\cdot}087$) were established between mineral frequency and sedimentary grade size, stratigraphical variates and grade size, etc., in the Top Ashdown Pebble Bed. These in turn led to further investigations which showed, for instance in the first example, that they were usually direct results of the interplay of former hydrodynamical conditions and the relative abundance of source materials. Post-depositional alteration was shown to have taken a very minor role.

Statistical Characterization of the Sediment as a Whole

The final statistical characterization of the entire horizon is most conveniently given by the arithmetic means, standard deviations and standard errors of the frequencies, abrasion indexes, size indexes and sorting indexes of each mineral and pebble species, variety, form, etc., together with the significant correlations (qualified by their standard errors) established between certain of these variates. This should be regarded merely as a development of Butterfield's pregnant creations—his "characteristic formula" and "range formula"[3].

The problem of comparing and contrasting sediments with sediments and other rock types by means of characteristic statistics is still under investigation. Though the possibilities of using r and χ^2 appear promising in this respect[4,5], the difficulties of translating the statistical into geological correlations remain unsurmounted. Until, by their combined efforts, petrologists amass a fairly large sample of all such statistical relations, we can have no basis for making direct petrogenetical probability statements. The frequency suites of the arbitrary Ashdown horizon previously mentioned and of certain Yoredale Sandstones[3] yield (at present) $r = + 0{\cdot}89 \pm 0{\cdot}093$, but our ignorance of the geological status of this value

forbids us to conclude that it necessarily implies a close genetical relationship.

A full exposition of the statistical methods outlined above will be given elsewhere in due course.

OBITUARY

Dr. H. D. S. Honigmann

DR. H. D. S. HONIGMANN, formerly director of the Zoological Gardens at Breslau, and recently scientific adviser to the Dudley Zoo, who died on November 17, was born at Breslau on July 5, 1891. He was educated at the Johannes-Gymnasium at Breslau, whence he proceeded to study zoology, physics and philosophy at the Universities of Breslau and Heidelberg. In 1916 he graduated at Breslau under W. Kükenthal; his thesis for his doctorate was on the primordial cranium of the hunchback whale. On his demobilization in 1918 he decided to round off his biological training by the study of medicine, and in 1921 he graduated in this subject with a thesis on parasitic flagellates of the human lung.

In 1927, after a few years of work as medical practitioner and public health officer, Honigmann was appointed director of the Zoological Gardens at Breslau. This appointment opened up for him a sphere of work which had been his ambition from early boyhood—the keeping, rearing and observation of animals. After years of war and post-war depression, it fell to him to rebuild and modernize the Breslau Zoo, a task which he performed with outstanding success. A number of scientific publications on observations on zoo animals were a by-product of this activity. He had just completed elaborate plans for a modern aquarium when his work was interrupted in 1934 by political events in Germany. He resigned his post and went to London where, following an invitation by Dr. Julian Huxley to work at the London Zoo, he carried out a series of studies on the nutrition of mammals, which led to the publication of a number of papers on the subject. His appointment in 1937 as scientific adviser to the newly founded zoo at Dudley gave him ample opportunity to make use of his wide experience in the scientific management of a modern zoo.

The outbreak of the War having brought his work at Dudley to an end, Honigmann took the post of science master at Blundell's School at Tiverton, whence the vicissitudes of the War took him to the Zoology Department of the University of Glasgow. There, on the invitation of Prof. E. Hindle and supported by a grant from the Society for the Protection of Science and Learning, he carried out a series of investigations in animal psychology, including work on the number conception in the fowl, a critical review of the problems of number conception in animals in general, and an analysis of movement vision in toads. His remarkable skill in the planning and execution of accurately controlled experiments, his thorough knowledge of the intricate problems of animal psychology, and not least his patience and experience in the handling of animals, make his publications in this field of lasting value; his last paper is still in the press and will appear in the *Proceedings of the Royal Society*. Plans for extensive further research in this field were frustrated by his death.

All who knew Dr. Honigmann will remember him as a scientific worker of great ability and experience, a warm friend and admirer of animals, and a person loved for his quiet charm, kindness and good-humoured companionship. OTTO LOWENSTEIN.

NEWS and VIEWS

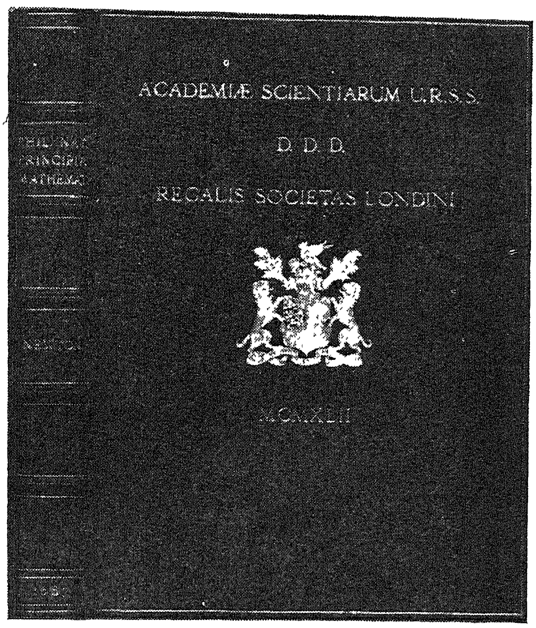
Jet-Propelled Fighter Aircraft

THE R.A.F. and the U.S. Army Air Force recently released information upon the progress made with jet propulsion for aircraft. The development of this for the R.A.F. is stated to have been in the hands of Group Captain F. Whittle, with the late Flight Lieutenant P. E. G. Sayer as test pilot. The special engine was built by Power Jets, Ltd., and the original aircraft by the Gloster Aircraft Co., Ltd. Experiments were afterwards continued in conjunction with the U.S. authorities, and further engines and aircraft were built in the United States by the General Electric Co. and the Bell Aircraft Co. respectively. These experiments have produced an aircraft judged to be sufficiently successful to warrant a partial adoption of the type, and production is now in hand of a sufficient quantity for training purposes in both countries.

The principle used in these machines is that air is taken in at the front of the body, compressed and heated, and exhausted at the rear end with increased velocity and temperature. The reaction produced is an axial thrust that replaces the normal propeller thrust. In general its efficiency would be greater, and there are additional practical advantages. The practical limitation in propeller diameter has already been reached, and some other way of turning the engine power into a propulsive thrust is necessary if any further increase in the power of individual engines is envisaged. Driving several airscrews from one engine has many practical limitations, the weight and unreliability of the transmitting mechanism being the principal, but by no means the only, trouble. Gyroscopic effects and the rotation of the slip stream are also eliminated by the absence of the rotating airscrews. Ground or water clearance can now be less if either structural or aerodynamical considerations demand it, as the propeller diameter no longer governs this. The first public claim to have produced a successful jet-propelled aircraft was made in Italy in December 1941, when it was stated that a Caproni-Campini C.C.2 machine flew from Milan to Rome at an average speed of 130 m.p.h. Speeds of this order have no application in modern war aircraft, but there is no reason why larger engines giving greater powers should not be built, when once the success of the principle is established.

Newton's "Principia" for the U.S.S.R.

On January 6 an interesting ceremony took place in Moscow. At the request of the Royal Society, H.M. Chargé d'Affaires presented to a deputation representing the Academy of Sciences of the U.S.S.R. a copy of the first edition of Newton's "Principia", together with the original draft of a letter by Newton to Prince Alexander Menshikov, acquainting the latter with his election into the fellowship of the Royal Society in 1714. The book, handsomely bound in



polished Levant morocco by the famous firm of John Gray and Sons of Cambridge, has an added value, because affixed within it is a sheet of vellum on which are recorded the signatures of the President and Council of the Royal Society in office when the gift was authorized. So far as can be ascertained, this is the only copy of a first edition of Newton's great work possessed by a scientific body in the U.S.S.R. Owing to indisposition, the President of the Academy could not be present when the gift was made; his place was, therefore, taken by the first deputy president, Academician Baykov. Incidentally, Prince Alexander Menshikov, a spectacular figure in the Russia of Peter the Great, was the first Russian to be elected into the fellowship of the Royal Society.

Prof. Vladimir A. Obruchev

The news that the honour of the Order of Lenin has recently been conferred on Prof. Vladimir A. Obruchev will be warmly welcomed by his admirers throughout the scientific world. Previously, his outstanding services to the U.S.S.R. had been recognized by his appointment as Cavalier of the Order of the Red Banner. In the minds of geographers and geologists, the names of Obruchev and Siberia are indissolubly linked. For more than a generation, Prof. Obruchev's studies of the stratigraphy, mountain-building movements and physiography of the eastern half of the vast Russian territory have earned our gratitude and respect, and his great work on the geology of Siberia (to which he has recently added a fifth volume) has become a classic. But a few decades ago, this huge region was one of the least-known areas of the globe. Prof. Obruchev's earlier expeditions and investigations of the rock succession and tectonics laid the foundations for economic developments on an astonishing scale. At an early stage of the work, he carried out the survey for the location of the Trans-Siberian railway; later, in furtherance of the far-sighted policy of the Government of the U.S.S.R., he contributed to the transformation of the country into one of the great mineral-producing regions of the earth—a story reminiscent of a fairy-tale.

Under Obruchev's inspiration, his colleagues and assistants set out to discover and exploit the mineral wealth which was to prove so essential after the German occupation of western Russia. Their activities were directed to the finding of ores of aluminium, copper, gold, iron, manganese, mercury, nickel, niobium, tin and tungsten, as well as non-metals like coal, oil and diamonds. In most cases, outstanding success crowned their efforts: in particular, the development of new goldfields owes much to Obruchev's own work. Not content with thus awakening many parts of the great area by harnessing its resources for future use, Prof. Obruchev founded in 1939 an Institute (named in his honour the Obruchev Institute) for the study of permanently frozen soil. Such soil indeed covers one third of Russian territory, so it is not surprising that the Government encouraged the Institute (in which ethnographical studies also find a place) with funds for extensive research. In 1941, when Moscow was threatened, the Academy of Sciences was evacuated to Sverdlovsk. It is satisfactory to learn that the Academy, and Prof. Obruchev, have now returned to Moscow, and that Prof. Obruchev celebrated there his eightieth birthday (on October 10 of last year).

Askanya Nova Nature Reserve

According to news reaching Great Britain, the State nature reserve at Askanya Nova, near Melitopol, in the southern Ukraine, has been completely devastated during its occupation by the German army, which evacuated the area some weeks ago. The reserve comprised a vast area of virgin steppe, where, side by side with the undisturbed flora and fauna, typical of the southern Ukrainian steppes, a large number of introduced animals and birds have been bred for years under natural conditions. A field biological station, laboratories, museum and a library were attached to the reserve, which presented unique opportunities for researches in plant and animal ecology, for experiments in the acclimatization of introduced animals and birds, etc. It is now reported that most of the animals and birds, that were living free, were killed by German hunting parties specially organized for the purpose, while the wire enclosures of others were smashed by tanks and the inhabitants killed off wholesale. Some of the more valuable animals were, however, taken away to Germany; for example, two of the three wild Mongolian horses (*Equus Przhevalskii*) were taken, the third killed. The few bisons were also killed. Most of the museum collections of birds and animals were transported to Germany, but the rich herbarium, insect collection and the library of more than 25,000 volumes were burnt. The removal of collections to Germany was carried out under the supervision of experts sent for the purpose.

Industrial Research and Taxation

THE long memorandum on "Post-war Industrial Reconstruction" issued by the Internal Combustion Engine Manufacturers' Association covers a wide field and quotes extensively from the League of Nations report on "The Transition from War to Peace Economy". While some of its proposals regarding the disposal of Government stocks of internal combustion engines after the War may be open to objection—the suggestion that the balance, after meeting the needs of devastated countries, providing a war reserve, and improving training equipment at engineering schools and technical institutions, should be disposed of by an organization, representing the industry and the Government, in the way best calculated to promote the national development and least likely to affect adversely employment in the industry, is somewhat naive—the report is yet another document emphasizing the importance of research. Dispersal of the industry's skill would undoubtedly be against the national interest, but the interests of producers can scarcely be allowed to dictate the disposal of surpluses, and the memorandum itself recognizes the necessity of continuing some national and international controls after the War, and on the whole shows a wide outlook and a readiness for more fundamental changes than mere attempts to mend the rents in the old pre-1939 patterns.

In regard to research, the memorandum urges that the position in regard to finance and especially the high level of taxation is a main reason for the inadequate prosecution of research in Great Britain. It suggests that all research expenditure should be allowed for taxation purposes, either when incurred or over a period of years, depending on the nature of the expenditure. Capital expenditure, such as that on laboratories and plant, and on patents, new designs and development to the commercial stage, should be granted relief on the basis of an allowance over a reasonable period of years. Research expenditure which is a normal incident of an efficient and progressive business should be allowed as and when made. Contributions to research organizations should be allowed similarly or, in special circumstances, spread over a reasonable period of years. Appropriate wear and tear allowances should be granted on plant and machinery acquired for the purposes of research, and if such plant and machinery is scrapped, any loss thereon, less any prior wear and tear allowance, should be allowed. The memorandum stresses the importance of clarifying the position as soon as possible, so that manufacturers can embark on an adequate programme of research and development with the knowledge that all such expenditure will rank for taxation relief.

"Political and Economic Planning"

THE Broadsheet "P E P Work, 1940–43", recently issued by Political and Economic Planning (No. 215, December 14, 1943), includes a summary of the present programme, as well as a note on some recent publications on "Research and Industry", and a complete list of P E P broadsheets and reports during 1933–43. Nine groups are in more or less regular session, and at least five full-scale reports are planned for 1944. One of these is a comprehensive report from the Fuel Group on the co-ordination of the fuel industries considered as a whole. The Population Policies Group, which is run jointly by P E P and the Eugenics Society, has begun to meet again, and it is hoped to publish a full-scale report as well as a number of broadsheets during 1944. A new edition of the P E P Report on the British Health Services is in prospect and a fully-fledged Health Group has again begun to meet regularly. The Physical Planning Group has concentrated attention in the past year on the complex social and economic factors influencing the pattern of physical planning and on the human needs to be satisfied, and in addition to further broadsheets a report will be published in 1944.

The Economic Outlook Group of P E P is conducting an investigation into the structure and functions of trade associations, and a broadsheet will be published early in the year. The International Group, from the publication of a forthcoming broadsheet on world political structure, will be replaced by an International Trade Group, the aim of which will be to present the facts about Britain's post-war export problem in its world setting. The Machinery of Government Group has completed two stages of its examination of the need for adjustment so as to make government the nation's common effective instrument for expanding its social and economic welfare, and when reconstructed this Group will tackle the problem of associating the ordinary citizen more closely with the process of local government. A special-purpose group to consider the future of Government information and publicity will follow the broadsheet on "The Future of Foreign Publicity" with one on home publicity. The work which formerly fell to the Partners in Industry Enquiry has again been taken up and several chapters drafted of a report on industrial relations, while further investigations are being made into the structure of industrial relations at the national, district and works levels.

Progress in Bacteriological Technique

PROF. J. CRUICKSHANK has prepared for the British Council an account of recent advances in bacteriological methods (*Brit. Med. Bull.*, 1, No. 8; 1943). The principal advances in the last ten years have, in his opinion, been made in the discovery of more efficient selective culture media for the isolation of bacteria, in the determination of the stable sub-groups or types of bacteria and in the development of typing methods which make it possible to trace the probable source of an infection or an epidemic. Antigenic analysis has resulted in such valuable discoveries as the Vi or virulence antigen of the typhoid bacillus. Antityphoid serum made for therapeutic use should contain Vi antibodies. The blood of typhoid carriers almost always contains these, so that the Vi agglutination test has become a valuable means of helping to trace the sources of the infection. The discovery of a Vi bacteriophage, which has a specific action on Vi strains of typhoid bacilli, can be used for the identification of particular strains of these bacilli. Epidemiologists have used this means of tracing the source of isolated infections or epidemics. The typing of diphtheria bacilli has also produced valuable results.

Work on the hæmolytic streptococci has revealed, by the extraction from these streptococci of a carbohydrate substance which gives a precipitation reaction in the presence of the appropriate anti-serum, thirteen groups of these streptococci. The streptococci of major importance in human infections belong to Group *A*, and at least twenty-three types of these have been identified. It has been found that the

same hæmolytic streptococci can give rise to various manifestations in a single community. At Queen Charlotte's Hospital in London, this typing method has provided the valuable information that, in puerperal fever, infection of the placenta by organisms in the genital passages at the beginning of labour is almost a negligible cause of puerperal fever; the important sources of infection are the attendants or other contacts, or even the upper respiratory passages of the mother herself. Similar work on the staphylococci has not yet given such striking results, but it is proceeding. The War has, of course, greatly stimulated work on organisms of the gas-gangrene group. Methods of growing anaerobic bacteria in the presence of air have been devised, and they have been grown on ordinary broth or peptone water containing a small strip of sheet iron.

A Film of Hospital Treatment

A REMARKABLE film, made by Gaumont Instructional Films, which is being shown under the auspices of the British Council, shows the successful operation by a British surgeon for the removal of the whole lung. The pictures are so taken that the spectator sees at least as much as, if not more than, most of the surgeon's assistants. At the beginning of the film the patient is shown, with his fellow workers in a factory, undergoing routine examination of the chest by X-ray. A cancer of the root of the lung is suspected in him, and the diagnosis is discussed by several experts in the light of subsequent examinations. Operation is decided upon and the patient sees the hospital almoner, who relieves his anxiety about the welfare of his wife and family while he is away from work. The special methods of anæsthetizing the patient are then shown and the operation itself follows, the spectator seeing the beating heart, the ligature and division of the pulmonary veins and the bronchus and other details. The rest of the film shows the after-care of the patient and his rehabilitation in a convalescent home until he returns to work. The British Council's chief function is, of course, to make British institutions and methods known abroad. This film, however, might well be shown widely in Great Britain.

Women's Health in War-time

IN a note entitled "Healthier Women—a War-time Asset", the *Statistical Bulletin* states that comparison of the mortality of women in the United States for the two years prior to the entry of that country into the War of 1914–18 with that for the two years (1940–41) before Pearl Harbour shows that women were benefited by the increasing control over disease. During this 25-year period, the death-rate among women insured in the Industrial Department of the Metropolitan Life Insurance Company, New York, has been reduced by about half. There were thirteen deaths in every 1,000 women aged from 15 to 74 in 1915–16 as compared with only seven in 1940–41. The decline in mortality from tuberculosis has contributed more than any other factor to this remarkable record. The control of pneumonia has also contributed much to the improvement in the total mortality among women. Diseases associated with pregnancy and childbirth have been sharply reduced since 1918. Diabetes alone has increased in the past twenty-five years among women. As regards suicide, the death-rate among insured women in 1940–41 was about two thirds the rate in 1915–16, and for accidents the proportion was three fourths.

An Ultra-High-Speed Motion-Picture Camera

ACCORDING to an article by H. J. Smith (*Bell Lab. Rec.*, 22, No. 1; October 1943) a new high-speed camera, known as the Western Electric Fastax High-Speed Motion-Picture Camera, is capable of taking pictures at the rate of 8,000 per second. Fastax cameras are made in both 8 mm. and 16 mm. models. The 8 mm. model will take from 300 to 8,000 pictures per second, depending on the voltage applied to the motors, while the 16 mm. model will take from 150 to 4,000 pictures per second. Approximately full speed is obtained at nominal line voltages from 110 to 125 volts. To secure lower speeds a rheostat may be placed in series with the motor to reduce the applied voltage.

These new cameras are of the continuous-motion type employing an optical compensator, or rotating prism, between the lens and the sprocket. The 8 mm. camera has an eight-sided prism permitting eight pictures per prism revolution, and the 16 mm. camera has a four-sided prism permitting four pictures per prism revolution; each revolves in synchronism with the film. The prism creates successive and properly spaced images travelling with the film. The image gathered by the lens is refracted by the prism upward to meet the incoming frame, and as the frame advances downward, the image follows, thereby permitting continued exposure throughout the period that the film travels past the aperture. The duration of the exposure is controlled by the speed of rotation of the prism. Both these cameras are arranged to use either 100-ft. or 50-ft. spools of film. At top speed the film travels through the camera at about 70 miles per hour, the exposure time per frame being about 1/30,000 sec. for the 8 mm. camera and 1/12,000 sec. for the 16 mm. camera. At full voltage one hundred feet of film runs through the camera in approximately 1·25 sec. The motor driving mechanism is described in the article.

Physical Significance of Maxwell's Theory

IN a lecture delivered by Mario Bunge on June 21, 1943, before the Faculty of Industrial and Agricultural Chemistry of the National University of Litoral, under the title "Significado Fisico e Historico De La Teoria De Maxwell", the work of Maxwell is considered, and its influence in his own day and also on posterity is dealt with (Buenos Aires: Universidad Obrera Argentina. Pp. 16). Among the important effects of Maxwell's theory may be noted the downfall of mechanism for the second time in history. The first non-mechanical theory was the undulatory theory of light under Huygens, Fresnel, MacCullagh, Green, Cauchy, etc., and now for the second time physics seemed to be released from the thraldom of mechanism. The opinion of Gustavo Avé Lallemant, one of the few authorities on physical science in the days of Maxwell, is worth recording. He said that the English, so practical, had created a new science, "la Electrometria", which teaches us how to calculate all the effects of electrical phenomena, though adding nothing to the manner of explaining the nature of electricity (*Anales de la Sociedad Cientifica Argentina*, **13**, 193; 1882). For Maxwell a model was simply a method for teaching but not a real need, and he was convinced that electromagnetism was not reducible to mechanism. In conclusion, it is pointed out that Maxwell's theory has developed in its form and consequences in such a manner, that in the mechanics of de Broglie, Schrödinger, Heisenberg, Born and

Dirac, not only has there been a unification in electromagnetism and optics, but these have also been unified with mechanics. The evolution of physics has therefore followed, to a considerable extent, the pathway marked out by Faraday and Maxwell.

Riboflavin Deficiency in Fowls

DEFICIENCY of riboflavin (vitamin B_2) in chick rations leads to poor growth and may give rise to 'curled toe paralysis'. Where skim milk is available, this trouble is unlikely to occur; but under war-time conditions rearers are forced to depend chiefly on mashes. Official regulations have ensured that all rearing mixtures contain adequate riboflavin; but owing to the fact that essential ingredients such as dried skim milk and dried yeast are in short supply, the possibility of using an alternative source of the vitamin has been investigated by the Chemical Division of the Agricultural Research Institute of Northern Ireland. The results are published in its sixteenth Annual Report, 1942–43. Chicks were reared from hatching to fourteen days on a basal ration adequate in protein, minerals, and vitamins A and D but deficient in riboflavin. They were then divided into groups and supplied with various levels of either dried skim milk or dried liver in addition to their basal ration, one group continuing on the basal ration alone. 5 per cent dried liver was slightly more effective than 10 per cent dried skim milk for growth, and no cases of 'curled toe paralysis' occurred in either group. So little as 1 per cent dried liver improved growth but was insufficient to prevent the leg weakness. A further test fully confirmed these results and also showed that 10 per cent dried lung was as good as 5 per cent dried liver, so that both meals may prove a valuable new source of riboflavin-rich protein supplement for chick-rearing rations. A small stock of these meals has been produced, and work on the subject is being continued.

Literature of Rheology

IN the August issue of the *Rheology Bulletin*, published by the Society of Rheology under the auspices of the American Institute of Physics, a new feature, "Rheology Reviews", is started with a survey by Dr. R. Dow of "Some Rheological Properties of Matter under High Hydrostatic Pressure". It is intended that the new series shall furnish a perspective of a wide field of knowledge, and that each survey shall be prepared by an expert in the field. In the same number more than twenty pages of abstracts are given. The journal is published quarterly from 175 Fifth Avenue, New York, N.Y., and was founded to help workers in the fields of elasticity, viscosity, plasticity and the like, to a better understanding of their common problems. It was created as a medium for the exchange of information as to theories and methods relating to the rheological properties of matter. The issue for November 1942 contains details of the contents of the *Journal of Rheology* published by the Society during 1929–33. In 1933 the new journal *Physics*, now called the *Journal of Applied Physics*, began to publish the rheological material. Incidentally, the *Bulletin* illustrates a cheaper method of publication of journals with a small circulation: the matter is prepared on a typewriter with graphs and the mathematical parts added by hand. The copies are then printed by the use of photo-lithography.

Electrolytic Production of Hydrogen and Oxygen

"The Production of Hydrogen and Oxygen by the Electrolysis of Water" is the subject of a paper (*J. Inst. Elec. Eng.*, 90, Pt. 1, No. 35; Nov. 1943) by Mr. C. E. Bowen, which reviews the principles and practice of the electrolysis of water and discusses its interest to the electrical engineer. Following the chemical expression of the process, the various factors influencing the yields and power requirements are considered. In the theoretical treatment, the application of Faraday's law is discussed, together with the question of current efficiency. The factors controlling the cell voltage, such as minimum-decomposition voltage, over-voltage, current density and resistance of electrolytes are studied, data being supplied as a guide to the general design requirements of this type of equipment. Methods and materials of construction are also discussed, with some notes on the handling of the gases. The paper describes some modern types of apparatus, and the performance of the equipment is illustrated. The demand for the two gases is discussed and some of their uses are defined. Finally, the author suggests, on the basis of some of the figures included, that the large amounts of power concerned should be of the greatest interest to electrical engineers.

Anti-malaria Campaign in Panama

A RECENT paper (*Bol. Of. San. Panamericana*, 22, 502; 1943) published by the Malaria Section of the Ministry of Public Health and Public Works of Panama contains an account of the following means adopted against malaria in Panama. More than 300 Anopheles breeding places in the towns of the interior are regularly kept under control by weekly inspection and identification of the larvæ. Eight species of Anopheles have been identified, namely, *A. albimanus, argyritarsis, pseudopunctipennis, apicimacula, albitarsis, strodei* and *neomaculipalpus*. The methods most favoured include the use of oil and Paris green. Paris green, which destroys only the larvæ, is preferred owing to the economy in use and facility of transportation. An approximate idea of the incidence of malaria in the different regions can be obtained from the incidence of malaria mosquitoes and the splenic enlargement and parasitic determination in school children. Rainfall records in infested regions are also of help. Sanitary education by lectures, cinemas, meetings, etc., is slowly progressing.

Treatment of Peripheral Nerve Injuries

THE *British Medical Bulletin* is published monthly by the British Council for distribution abroad. Each number contains, in addition to valuable summaries of British research papers of medical interest, a special summary of recent work in some field of inquiry, which is written by an authority on that subject. Prof. H. J. Seddon, in an issue devoted to peripheral nerves, writes upon peripheral nerve injuries (*Brit. Med. Bull.*, 1, No. 7; 1943). Clinical problems presented by nerve injuries have not, he says, received great attention except during times of war, when injuries of peripheral nerves are commoner than they are in normal times. The increasing mechanization of our civilization may, however, result in an increase of peripheral nerve injuries even in times of peace. In 1940 the Ministry of Health and the Medical Research Council established, at civilian hospitals in the Emergency Medical Service,

five centres for the treatment of nerve injuries, three in England and two in Scotland. Similar centres have been organized in Natal, India and the Middle East. Treatment often extends over long periods and rehabilitation is both general and specific, the former being designed to keep men fit mentally and physically and the latter to encourage fine co-ordinated movements and the recovery of tactile discrimination. It is often possible for a man to return to work or to military service before recovery is complete. R.A.F. pilots are even able to return to operational flying before they have completely recovered. While complete restoration of function occurs in only a minority of cases, it is remarkable how many patients are able either to return to their former work or to train for new jobs.

Research is also carried out at these beneficent centres. It provides a check on the efficacy of the treatment given and a clearer definition of the various types of injury. Much information is obtained by special methods of examination which could not be obtained in any other way. Animal experiments are also used, and Prof. Seddon thinks that only the balanced combination of this and clinical observation can provide steady progress. The help of the modern highly-trained veterinarian might well be enlisted here. Between three and four thousand cases have already been treated at these centres and, as Prof. Seddon says, the mass of information which is being obtained should greatly advance this branch of neurology.

Emergency Lighting Systems

A PAPER on the applications of emergency lighting systems with particular reference to battery equipments was read before the Institution of Electrical Engineers in London on November 11 by Mr. S. H. Chase, who pointed out that in recent years there has been an increasing call for the installation of emergency lighting systems. These can be provided by candles or nightlights, gas, dry- or wet-battery torches, accumulators, engine-generator sets, alternative independent mains supply, or by a combination of several methods. The amount of emergency lighting may range from an intensity equal to normal down to the minimum considered necessary for safety and continuation of essential services. The paper deals mainly with the use of accumulators for standby purposes, operated either manually or automatically upon failure of the mains supply, and capable of supplying loads for varying periods according to the class of installations, which are grouped under five heads: theatres and cinemas, hospitals and nursing homes, public buildings, etc., factories and A.R.P. services.

Modern Insulating Materials

IN a paper on "The Control, Specialized Testing and Use of Some Modern Insulating Materials", Mr. A. R. Dunton (*J. Inst. Elec. Eng.*, 90, Pt. 1, No. 35; Nov. 1943) deals briefly with the details associated with the control of incoming materials to the factory, together with some special features associated with tests which have to be carried out in order that the performance of the materials under special conditions can be ascertained. To achieve this work, special testing apparatus has been designed from time to time, and brief reference is made to some of the problems which have to be solved in order to ensure that the insulating materials selected will fulfil the performances required. Suggestions are also made dealing with the question of finding substitutes for insulating materials in short supply, and some of the new materials introduced for this purpose are mentioned.

Announcements

DR. R. E. PRIESTLEY, vice-chancellor of the University of Birmingham, has been appointed an additional member of the Commission on Higher Education in the Colonies. The appointment has been made in consideration of the fact that Prof. A. V. Hill's absence in India makes it impossible for him to take part in the proceedings of the Commission for some time.

DR. H. W. THOMPSON, lecturer in chemistry in the University of Oxford, will deliver the Tilden Lecture of the Chemical Society on January 20 at 2.30 p.m.; he will speak on "The Scope and Limitations of Infra-Red Measurements in Chemistry".

THE trustees of the Miners' Welfare National Scholarship Scheme, established by the Miners' Welfare Commission for the provision of university scholarships for workers in or about coal mines and their sons and daughters, have appointed Principal J. F. Rees, of the University College of South Wales and Monmouthshire, Cardiff, to be a member of the selection committee to recommend awards under the scheme, in succession to Prof. J. F. Duff, who has retired after completing five years on the committee.

THE Therapeutic Corporation of Great Britain has elected the following officers for the year 1944: *Chairman, Board of Directors:* Mr. H. Jephcott (Glaxo Laboratories, Ltd.), (succeeds Dr. T. B. Maxwell, May and Baker, Ltd.); *Deputy Chairman, Board of Directors:* Dr. F. H. Carr (The British Drug Houses, Ltd.), (succeeds Mr. H. Jephcott, Glaxo Laboratories, Ltd.); *Chairman, Research Panel:* Dr. A. J. Ewins (May and Baker, Ltd.), (succeeds Dr. F. L. Pyman, Boots Pure Drug Co., Ltd.); *Deputy Chairman, Research Panel:* Mr. F. A. Robinson (Glaxo Laboratories, Ltd.), (succeeds Dr. J. W. Trevan, The Wellcome Foundation, Ltd.). The Corporation has appointed Dr. Frank Hartley as secretary, to take up duties early in 1944. The new offices of the Corporation are at General Buildings, 99 Aldwych, W.C.2.

A COURSE of twelve lectures on "The Psychology of Frustration and Fulfilment in Adolescence" has been arranged by the National Council for Mental Hygiene. They are being delivered in the Caxton Hall, London, S.W.1, on Tuesdays, beginning January 18, at 5.15 p.m. The lectures are specially addressed to those with social and educational interests. Dr. J. A. Hadfield will speak on the psychology of adolescence; Dr. Paula Heimann on the psychoanalytic approach; Mr. R. W. Moore, headmaster of Harrow School, and Mr. T. F. Coade, headmaster of Bryanston School, will discuss the teacher's approach to the problems of the adolescent boy; Miss L. V. Southwell, headmistress of St. George's School in Switzerland, will deal with the adolescent girl in boarding schools; and Miss Olive Willis, headmistress of Downe House, Newbury, will discuss the teacher's approach to the problems of the adolescent girl. Tickets (single lectures, 3*s.* 6*d.*; course, £1 10*s.*) can be obtained from the Secretary, National Council for Mental Hygiene, 39 Queen Anne Street, London, W.1.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Adsorption as the Cause of the Phenomenon of the 'Floating Drop', and Foam consisting solely of Liquids

DROPS of a liquid may be floating on the surface of the same liquid before coalescence occurs. This 'phenomenon of the floating drop', as it may be called, was apparently first described by O. Reynolds in 1881. It was investigated by E. Kaiser (1894) and explained as due to the presence of an air layer between the drop and the surface of the bulk liquid. L. D. Mahajan, in numerous papers (1929–34), studied the phenomenon, concluding that it was due to a 'cushion' of air or other surrounding medium (kerosene or olive oil); the more viscous this medium, the more stable are the drops. F. H. Hazlehurst and H. A. Neville[1] extended the study to drops floating on a surface of another liquid. They rejected the previous interpretations, and assumed "that the surface of any liquid is quasi-solid, being composed of crystallites".

Having given a good deal of attention to this phenomenon—primarily without knowledge of the previous work—we have been led to the general view that *the phenomenon of the floating drop is caused by the adsorption of a foreign substance at the surface of the liquid*; the greater the viscosity appearing at the surface, the higher is the stability of the phenomenon.

Some observations supporting this view may now be given. Ethanol, considered earlier to be one of the most effective liquids in showing the phenomenon, was found to give floating drops lasting about 8·0 sec. in ordinary air (Fig. 1). In dry air the life-time of the drops was only 0·7 sec. Hence, in ethanol, the phenomenon is essentially due to the adsorption of moisture from the air. In an evacuated apparatus the phenomenon disappears entirely. Hence, the (less marked) phenomenon still appearing in dry air must be caused by the adsorption of air. This was further supported by the fact that a thin (0·4 mm.) ethanol jet in air, when so long (more than 30 mm.) that no floating drops appeared, gave rise to numerous air bubbles in the bulk liquid; when the length was less than 30 mm., with a lot of floating drops appearing, the air bubbles ceased to appear.

In saponin solutions the life-time (τ) of the drops was found to be a function of the concentration (Fig. 2, I), with a maximum at 1 per cent. This is quite similar to that of known adsorption isotherms. If, immediately before the timing observations, a series of rapid droppings was made, the stability of the drops considerably increased (series II). This must be ascribed to an accumulation on the flat surface of saponin adsorbed on the drops, and evidence of the importance of adsorption.

Fig. 1.

Our observations emphasize the analogy between the phenomenon of floating drops and the formation of bubbles or foam. As a matter of fact, pure liquids are known not to foam; the main factor is adsorption, exerted by a capillary active substance; a high stability presupposes a certain viscosity of the adsorbed layer.

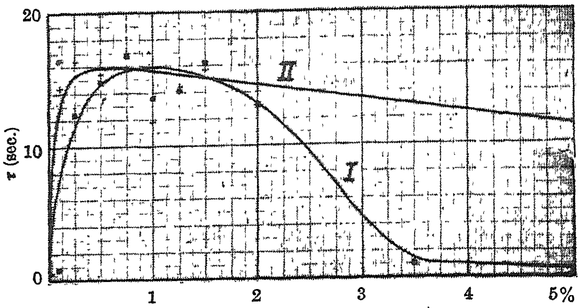


Fig. 2.

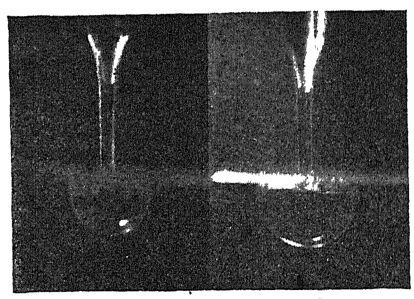
Saponin solutions, as is well known, form in air a rather stable foam. We observed that foam is formed by a saponin solution kept in an evacuated vessel, but the stability of this foam was found to be much lower than in air. Hence, we may conclude that foam, under ordinary conditions, is partly stabilized by an adsorbed layer of air.

In a similar way, the considerable stability of floating saponin drops must partly be due to adsorbed air: in an evacuated vessel, saponin solutions—under the conditions used—actually gave no floating drops.

Fresh malt beverage was found to give persistent floating drops (up to 28·6 sec.). When the carbon dioxide had been removed *in vacuo*, however, the life-time was only 0·2 sec. This is parallel to the fact that the foaming ceases when carbon dioxide is removed. Hence the adsorption of carbon dioxide in both cases exerts a considerable influence.



a b

Fig. 3.

Saponin solutions were found to give persistent floating drops not only in air but also in nitrogen and in oxygen as well; the stability was greater in nitrogen.

The explanation given by Kaiser and by Mahajan, implying that the phenomenon is caused by a thin foreign layer, obviously is in good harmony with our statement of the influence of adsorption. As for the assumption of Hazlehurst and Neville—implying that the 'foreign' layer would be composed of crystallites of the pure liquid itself—this appears now unnecessary and is scarcely in harmony with the fact that the phenomenon does not occur *in vacuo*.

With saponin solution, it was found possible to form rather large floating drops (11 mm. in diameter) by successively dropping on single drops. The foreign 'adsorbed' layer necessary may also be realized by using a thin layer of oil, spread on a water surface. When dropping on water, very large floating drops may be produced, as evidenced in Fig. 3, showing drops formed by the coalescence: in *a* of 30 single drops, in *b* of about 80 drops (diameter 16 mm.). These fairly stable spherically limited masses of water in water with an extremely thin oil layer remind one of the spherical oil masses in alcohol of the same density produced by Plateau.

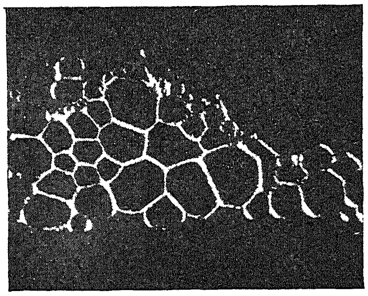


Fig. 4.

We were further led to the production of a foam, consisting solely of liquids. Such a 'liquid-foam' is evidenced by Fig. 4. The cell walls are saponin solution (0·5 per cent), the cell content is oil ('Lighthouse', Pratt), which has been introduced into the saponin solution—kept at the bottom of a thin cuvette.

The appearance of the fluid-foam was very similar to the 'gas-foam' formed in the same cuvette on introducing air into the saponin solution.

The main interest of the fluid-foam is that it affords a rather close analogy with the capillary grain structure of solid metals[2].

A detailed account of this work will appear in *Arkiv för Matematik, Astronomi och Fysik*, vol. 30 A, of the Royal Swedish Academy of Sciences, Stockholm.

Interpretation of Patterson Diagrams

PROF. J. MONTEATH ROBERTSON's communication on the above subject in NATURE[1] suggests a modified method, based on the same geometrical principle.

I refer now to the diagram in Prof. Robertson's communication. Let AA' and BB' be opaque screens pierced in the points 1, 2, . . . and 1', 2', . . . respectively. If AA' is illuminated from the left, the peaks in the Patterson diagram will appear on the surface CC'.

The two screens AA' and BB' can be rapidly prepared by punching circular holes in sheets of cardboard. The holes form the pattern of the projected atomic positions and the pattern on AA' may be drawn to a scale twice as large as that of the pattern on BB'. In this case the distance from AA' to BB' should be equal to the distance from BB' to CC'. The unit area will then be the same on AA' as on CC'. The integrated intensity of a projected Patterson peak will be proportional to the product of the areas of the two corresponding holes. If the distances between the screens are large compared with the extension of the atomic patterns, and if the holes in AA' and BB' are made to correspond to atomic contours, the contours of the Patterson peaks will be practically circular and the diameter of a circle will be the sum of the diameters of the two corresponding atom holes in AA'. Important features of the real Patterson function are thus rather closely attained.

The projection surface CC' is preferably a ground-glass plate, which is viewed from the right. The contours of the real Patterson diagram can be drawn on the ground-glass surface, thus enabling an easy comparison with the projected picture.

Compared with Prof. Robertson's method, the modified method outlined here lacks the possibility of continuous variation. However, the variation can be carried out quite rapidly, and the modified method seems to possess certain advantages in other respects.

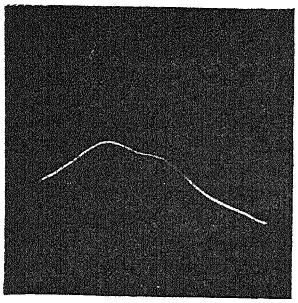
A New Type of Microphotometer

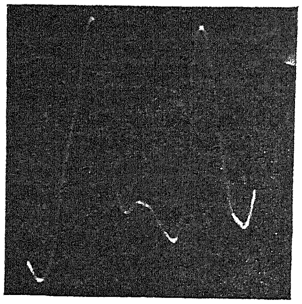
UNDER this title[1] R. Fürth gave a short description of an instrument designed for providing a practically instantaneous record on a cathode ray oscillograph of the density distribution along a short straight line on a photographic plate. This record was in fact obtained by the superposition of two traces writing in opposite directions on the screen of the cathode ray oscillograph, corresponding to the two directions of the vibrational motion of the plate through the slit image. A rather thick curve resulted, therefore, with loss in detail compared with the records of other existing types of microphotometers. In addition, fluctuations in frequency of the mains voltage by which the instrument is operated could cause slight displacements of the two traces[2].

A brief description is given here of an improvement on Fürth's microphotometer which has resulted in an increased resolving power and more satisfactory working conditions. It consists in the application between grid and cathode of the cathode ray tube of a periodic 'square wave' voltage which controls the brightness of the fluorescent spot on the screen in such a way as to make only one trace visible. To produce this voltage (which must be properly related to the time-base voltage) an electrical circuit is used which is comprised mainly of a 90° phase-shifting network with an amplifier the output of which is applied to a peak-clipping device.

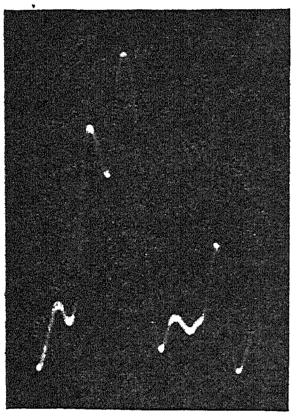
In order to demonstrate the improved performance of the instrument, three photographic records are shown relating to the density distribution in a photograph of the arc spectrum of copper in the neighbourhood of 3440 A., taken with an ordinary glass spectrograph. Records 2 and 3 (with original magnification of 30) each cover a range of 15 A. approximately. Record 1 is of the central hump in record 2; it corresponds to an original magnification of 200 and covers a range of 2·2 A., and a distance of 0·24 mm.



1



2



3

on the spectrum photograph. On the oscillograph screen a distance of 1 mm. corresponded to 0·3 A. in records 2 and 3 and to 0·045 A. in record 1.

These curves, in addition to giving evidence of the increased resolving power now available with the aid of this device (as will be seen by comparison with the first note on the microphotometer quoted above), serve to illustrate how the magnification of the instrument can be altered at will to study more closely any portion of the photometric curve.

A more detailed description of the device will be published elsewhere shortly.

Meiosis of a Triple Species Hybrid in Gossypium

SKOVSTED[1,2] brought forward considerable cytological evidence that New World ($n = 26$) cottons originated by amphidiploidy from crosses between ancestral Asiatic ($n = 13$) and American ($n = 13$) parents. Recently Harland[3] and Beasley[4] have independently synthesized by colchicine treatment amphidiploids from hybrids between present-day Asiatic and American diploid species. Since the synthesized amphidiploids produce partly fertile hybrids on crossing with present-day New World types, they contribute strong supporting evidence to Skovsted's theory. It should be pointed out, however, that such evidence can only be considered critical if it can be shown that genom combinations *other* than Asiatic + American do not pair equally well with the New World complement. I have brought forward[5,6] phenogenetic evidence which suggests that critical examination of Skovsted's hypothesis may now be confined to testing combinations between Asiatic species and one or other of several entire-leaved species. The following combinations should be worth testing:

(1)	Asiatic (A)*	+	*G. aridum*	(D)
(2)	Asiatic (A)	+	*G. klotzschianum*	(D)
(3)	Asiatic (A)	+	*G. raimondii*	(D)
(4)	Asiatic (A)	+	*G. sturtii*	(C)

* Letters indicate genoms according to Beasley's system.

It will be noted that all combinations except the fourth include an American diploid genom. Clearly if *G. sturtii* could be eliminated as a possible ancestor of New World cottons, Skovsted's hypothesis would be considerably strengthened. The low meiotic pairing found by Skovsted[2] in New World × *G. sturtii* hybrids (A C D) and the high pairing found by Beasley[7] in the corresponding hexaploid $(A\ C\ D)_2$ certainly do not suggest *G. sturtii* as a possible parent—a conclusion which is supported by the data presented below.

A triploid (A A C) was recently obtained by crossing an autotetraploid Asiatic cotton with *G. sturtii*. The meiotic behaviour of this hybrid has been fully reported elsewhere[8], when it was shown that homology between A and C genoms was very low. The triploid was treated with colchicine, and pollen from some of the distorted flowers produced during the ensuing abnormal vegetative growth appeared to be viable. New World species were accordingly crossed persistently with pollen from these flowers. A completely sterile hybrid with 52 chromosomes was eventually obtained from 103 attempted crosses. Since it is known that the New World female parent (*G. barbadense*) produced normal 26 chromosome gametes, the gametes from the male parent must also have contributed 26 chromosomes. Furthermore, since the hybrid had the distinctive mauve petal colour of *G. sturtii* and plant hairiness characteristic of the Asiatic type used—neither of which characters was carried by the *barbadense* parent—it was certain that both Asiatic and *sturtii* chromosomes had been included. With the knowledge that unbalanced gametes are very rare in Gossypium, and that *sturtii* and Asiatic chromosomes have low homologies, it seems likely that complete A and C genoms were contributed by the male parent. If this is accepted provisionally, the hybrid should have the following constitution:

$$♀ \rightarrow AD/AC \leftarrow ♂.$$

At meiosis the A genoms should pair as bivalents or higher associations, as shown by Skovsted's[1] Asiatic × New World hybrids, while the C and D genoms, if their pairing is similar to that found in Skovsted's[2,9] American diploid × *G. sturtii* hybrids, should show low and very variable pairing. Univalents should consist of two types—very large from the C set and small from the D set.

Meiotic studies of the hybrid agree reasonably well with expectation:

Cross	Average number of univalents per PMC	No. of PMC's examined	
Triple hybrid..........	11·8 ± 0·8	20	
Davidsonii × *sturtii*	15·0 ± 0·8	40	Skovsted's data
Sturtii × *armourianum*	8·5 ± 0·9	20	

Owing to the uniformly high variability, the number of univalents found in each hybrid barely differs significantly. A typical first metaphase plate of the triple hybrid is shown in Fig. 1. The great range in size of the univalents is apparent (see also Fig. 2), although I do not consider it possible to classify them *all* with certainty as C or D types. However, the evidence as it stands is sufficient to demonstrate, under identical cytological conditions, the low homologies existing between Asiatic, New

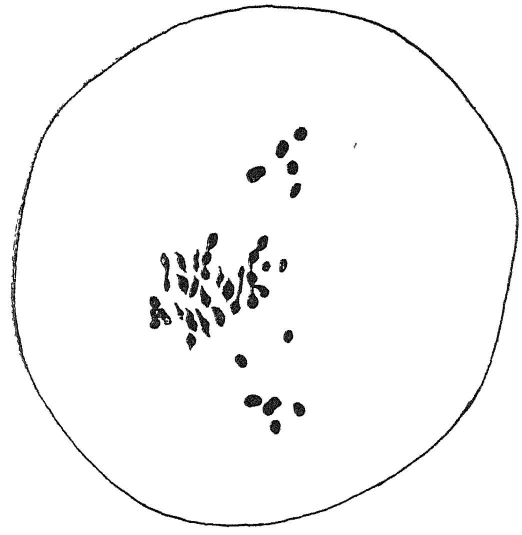

Fig. 1. METAPHASE I IN THE TRIPLE SPECIES HYBRID, *G. barbadense* × *G. arboreum* × *G. sturtii* (*A C D*) SHOWING 1 V, 2 IIIs, 14 IIs AND 13 Is. (× 1200).

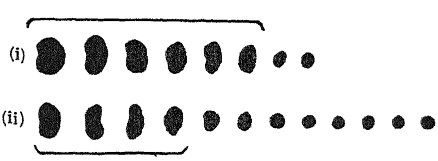

Fig. 2. UNIVALENTS FROM TWO OTHER METAPHASE I PLATES. PROBABLE *C* UNIVALENTS ARE BRACKETED. (× 1,800).

World, and *sturtii* genoms, and hence *G. sturtii* may be dismissed as a possible parent in the origin of New World cottons.

Development of Gametocytes from Extra-erythrocytic Forms in *Plasmodium gallinaceum*

IT was shown in a previous paper[1] that if fowls inoculated with emulsions of organs containing extra-erythrocytic forms of *Plasmodium gallinaceum* are subjected to intense and continuous quinine treatment (150 gm./kgm. body weight quinine hydrochloride daily), they eventually become heavily infected with extra-erythrocytic forms in the complete absence of erythrocytic schizogony. During quinine treatment the red cells become infected with small non-pigmented parasites derived directly from extra-erythrocytic forms. These small non-pigmented forms do not develop further unless the quinine is stopped or the dose diminished, in which case they undergo the normal cycle of development in red cells. The same results are obtained in birds subjected to the bites of infected mosquitoes, *Ædes ægypti*, and to continued intensive quinine treatment. With the interruption of quinine treatment the parasites in the red cells, all derived from extra-erythrocytic forms, undergo normal development which can be readily followed by examining the blood at various intervals.

Discussing these findings with us, Brigadier J. A. Sinton asked whether or not gametocytes are derived from extra-erythrocytic forms.

Experiments on birds infected by the bites of *A. ægypti*, and subjected to intense quinine treatment which was stopped only after red cells were infested with small non-pigmented parasites, showed beyond all possible doubt that among the merozoites produced by extra-erythrocytic forms some invade red cells and develop directly into gametocytes. Young gametocytes can be recognized $27\frac{1}{2}$ hr. after the cessation of quinine, and they approach their maximum size before the first cycle of erythrocytic schizogony is completed.

Effect of *p*-Amino-Benzoic Acid on the Toxicity of *p*-Amino-Benzene-Sulphonamide to Higher Plants and Fungi

MOST of the published observations on the antagonism between *p*-amino-benzoic acid and *p*-amino-benzene-sulphonamide relate to the growth of bacteria, but work carried out in these laboratories and elsewhere shows that this antagonism also obtains with higher plants and fungi.

Working with isolated tomato roots growing in tissue culture, Bonner[1] has described a growth inhibition caused by *p*-amino-benzene-sulphonamide which is reversed in the presence of *p*-amino-benzoic acid. More recently I have observed a similar response from complete plants growing under more natural conditions. In a series of experiments connected with the control of seed-borne fungoid diseases of wheat, the following observation was made. *p*-Amino-benzene-sulphonamide in fine powder form was applied to wheat at the rate of 0·01 per cent, and the grains were sown in soil. The emergence was markedly reduced, and those plantlets which did emerge were stunted. If the grains are soaked in aqueous solutions of *p*-amino-benzene-sulphonamide and are subsequently sown in moist sand at 22° C., percentage germination after five days is not affected, but the coleoptile and roots are stunted. Addition of *p*-amino-benzoic acid to the aqueous solution of *p*-amino-benzene-sulphonamide cancels this stunting effect, as is shown by the series of experiments recorded in Tables 1 and 2.

TABLE 1 MEAN PERCENTAGE GERMINATION OF WHEAT SEEDS: FIVE DAYS AT 22° C.

Concentration of *p*-amino-benzene-sulphonamide solution	Concentration of *p*-amino-benzoic acid			
	Nil	0·1 p.c.	0·25 p.c.	0·5 p.c.
Nil	100·0	100·0	100·0	100·0
0·5 per cent	100·0	97·3	98·6	100·0
1·0 per cent	100·0	98·6	100·0	96·0

TABLE 2. MEAN COLEOPTILE LENGTH (mm.) OF WHEAT SEEDLINGS.

Concentration of p-amino-benzene-sulphonamide solution	Concentration of p-amino-benzoic acid			
	Nil	0·1 p.c.	0·25 p.c.	0·5 p.c.
Nil	50·8	46·5	50·0	41·6
0·5 per cent	7·4	9·4	26·3	38·6
1·0 per cent	7·3	7·9	20·4	35·3

This result naturally led to the extension of the work to cover fungi as well as higher plants, but here it was found from the literature that Dimond[2] had already observed that *p*-amino-benzene-sulphonamide had a retarding effect on the dermatophytic fungus *Trichophyton gypseum*, which is antagonized by *p*-amino-benzoic acid. However, I have found that *p*-amino-benzene-sulphonamide has also a delaying effect on the early stages of germination and growth of the fungi *Penicillium digitatum* Sacc., *Fusarium caeruleum* (Lib.) Sacc. and *Botrytis Allii* Munn. This initial delaying effect is eliminated by very small concentrations of *p*-amino-benzoic acid. Various concentrations of *p*-amino-benzene-sulphonamide and *p*-amino-benzoic acid were included in a synthetic agar medium (Raulin-Thom) in Petri dishes. The surface was spread with a spore suspension, the plates incubated at 25° C., and the amount of growth recorded at intervals in arbitrary units. Addition of *p*-amino-benzoic acid alone in no way affected the growth of the fungi. Results of a typical experiment are shown in Table 3.

TABLE 3. EFFECTS OF *p*-AMINO-BENZOIC ACID AND *p*-AMINO-BENZENE-SULPHONAMIDE ON GROWTH OF *Penicillium digitatum*.

50	—	++	++	++	++	++
100	—	++	++	++	++	++

— no growth.
\+ reduced growth.
++ normal growth.

The generally accepted explanation of the antagonism between *p*-amino-benzoic acid and *p*-amino-benzene-sulphonamide, developed by Woods[3] and Fildes[4], is that *p*-amino-benzene-sulphonamide inactivates bacteria by virtue of a competitive inhibition of an enzyme reaction involving the utilization of *p*-amino-benzoic acid. From the results with higher plants and fungi now reported, it would appear, if the hypothesis of Woods and Fildes is accepted, that the enzyme reaction concerned is common to several widely distinct types of living organism. This suggests that it may eventually be found to be associated with some metabolic process of fundamental importance to living matter.

Mathematics of Biological Assay

IN a recent paper on "The Technique of the Biological Vitamin A Assay"[1], N. T. Gridgeman describes a method in which four equivalent groups of animals are given respectively doses D_s and nD_s of a standard preparation of known vitamin A content, and doses D_t and nD_t of the material under test. From their growth responses, G_s, G_{ns}, G_t, G_{nt}, the dose ratio D_t/D_s in terms of vitamin potency is calculated. Gridgeman assumes that the true relationship between growth G and dose D is of the form :

$$G = a + b.\log D + c.(\log D)^2, \quad . \quad . \quad . \quad . \qquad (1)$$

but employs a method of calculation in which the last term is ignored, that is, the relationship between G and $\log D$ is taken as linear. The slope b is calculated separately from the 'standard' growths and the 'test' growths, and the mean of the two values (which may differ significantly) is used to estimate D_t/D_s, again as the mean of the two possible values (see below). He shows for a typical set of figures that the result obtained does not differ, within the accuracy of the arithmetic, from the true value, and concludes : "This compensatory effect operates over fairly wide limits : it certainly covers all curves in our experience. An incidental inference is that a statistical demonstration of departure from parallelism in a biological assay is not necessarily evidence of the invalidity of the test".

I was led by these remarks to go further into the mathematics of the problem. Suppose that in the most general case the relationship between G and D is :

$$G = a + b.\log D + c.(\log D)^2 + d.(\log D)^3 + \text{etc.} \qquad (2)$$

Assume also that in a particular assay the *true* value of the ratio D_t/D_s is q. Following Gridgeman's method of evaluating this ratio, b is estimated as the mean of $(G_{nt}-G_t)/\log n$ and $(G_{ns}-G_s)/\log n$, that is, $(G_{nt}+G_{ns}-G_t-G_s)/2 \log n$. Denote this by b_e. The two available estimates of D_t/D_s, namely, antilog $(G_t-G_s)/b_e$ and antilog $(G_{nt}-G_{ns})/b_e$ are averaged for the final estimate, which is thus obtained from the equation :

$$\log \frac{D_t}{D_s} = \log n \left(\frac{G_{nt} + G_t - G_{ns} - G_s}{G_{nt} - G_t + G_{ns} - G_s}\right) \quad . \quad . \quad (3)$$

Now express the various G's as functions of the corresponding D's from equation (2) ; replace $\log n.D_t$ by $(\log n + \log q + \log D_s)$, and similarly for $\log D_t$, $\log n.D_s$; and expand second degree and higher terms where necessary. The resulting algebra is tediously lengthy, but many of the simpler terms cancel out, and the bracketed part of (3) reduces to :

$$\frac{\log q(2x + y_1)}{\log n(2x + y_2)}, \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad . \qquad (4)$$

where $x = b + c(\log q + \log n + 2 \log D)$, and y_1, y_2, are multinomials the coefficients of which are d and higher coefficients from (2).

Now over at least that part of the $(G, \log D)$ curve which is used in practice, and remembering the error inherent in biological assays, Gridgeman is perfectly justified in assuming the truth of equation (1), that is, in neglecting third and higher powers of $\log D$ in (3). This is equivalent to putting $y_1 = y_2 = 0$ in (4), and (3) then becomes :

$$\log \frac{D_T}{D_s} = \log n \left(\frac{\log q \times 2x}{\log n \times 2x}\right) = \log q, \text{ the true value.}$$

In other words, Gridgeman's method of calculation leads to a correct result, not because of a "compensatory effect" between "fairly wide limits", but because of a mathematical identity which is exact so long as equation (1) is true. Moreover, from a mathematical aspect, the intraclass dose ratio n and the interclass dose ratio q may both vary widely without affecting the validity of the calculations (though practical considerations may impose a restriction). Thus, Gridgeman's method is both of more general application and of greater mathematical rigidity than he supposes, and deserves the attention of all workers in this field.

Relation between Dissonance and Context

In view of the discussion with Mr. C. G. Gray[1] about the effect of context on dissonance, it may be useful to publish, with permission of the authors of the respective letters, certain criticisms which have been sent privately.

Prof. Cyril Burt is sympathetic with the hypothesis "that the dissonant character of a chord depends upon its context", but he wishes "to learn whether the musical experience and proclivities of the subjects made any difference to their reports". He himself attempted to test Helmholtz's theory of harmony "by means of correlating orders of dissonance and orders of pleasantness", and found that "the lack of correlation differed according to the musical experience of the examinees. Nearly everybody would rank the pleasantness of a major third far too high for the effect to be explained by absence of beats; but a few modern people would rank a tritone quite near the top. In fact, it seemed clear that, in ranking chords for their pleasantness, a large number of examinees were ranking them for their 'interesting' character. Thus an open fifth, though, according to Helmholtz's principles it should make a very good consonance, would be put near the bottom because it was devoid of interest". "Here again," he writes, "context makes all the difference. Beethoven's open fifth at the beginning of the Ninth Symphony actually heightens one's interest and curiosity just because of its non-committal character. In fact, here it almost seems to act like a dissonance. One seems to want a resolution in the sense of a major or minor third, so that one can at last feel assured what the actual key is going to be."

Dr. H. Banister is concerned about the effect of the equal temperament of the modern piano upon the character of chords, and thinks that it is not possible to assume, as Gardner and Pickford did, that a discord remains identical in dissonance when transposed in sequence. He, like Prof. Burt, also wishes to be assured that the subjects of the experiment were really judging dissonance and not some other quality, such as "interestingness". He thinks Helmholtz, who was concerned with isolated chords, might possibly have agreed with results in which dissonance-level varied with the context. He wishes to see the results of a more effectively controlled experiment.

Mr. Chalmers Burns finds it surprising that a psychological experiment should be necessary to prove what musicians have known for many centuries, namely, that the harshness of a dissonance depends on the way in which it is used.

Gardner and Pickford, who appreciate these criticisms, cannot say that they were unaware of them beforehand, and if they are able to publish any further interesting experimental results, they will do so; but it is worth saying that one subject in their experiment, who has some musical experience, reported that a certain discord sounded very dissonant until the progression in which it appeared reminded her of Debussy, and then it became consonant. Another subject, who has less musical experience, was unable to find any discords whatever in the whole experiment, though by musicians' standards some of them were certainly very harsh indeed.

Future of Quaternions

Prof. E. T. Whittaker, in his recent presidential address to the Royal Society of Edinburgh[1], has revealed the brilliant future which awaits the great Hamiltonian algebra in the domain of relativity.

Hamilton's great step forward in the initiation of his algebra lay in his perception that a vector could be used to indicate *either* a linear *or* an angular displacement. Further, the quaternionic algebra (with altered name) can be generalized to n dimensions. For example, in four dimensions, it is a vector volume that obeys Hamilton co-equally with the linear vector. There are also present vector planes both in and perpendicular to the three-dimensional constituent. The linear vector in the fourth dimension, taken as a Hamiltonian versor, at once indicates *no* fourth dimensional translation, but rotation in the three-dimensional constituent—the curved path of light.

Prof. Whittaker thinks that it was the physicists who neglected quaternions from their intrinsic mathematical difficulty. My experience has been different in dealing with students. It was the mathematicians who turned from the quaternionic algebra because of its summation of scalar and vector quantities. In view of their ready use of complex algebra, it is not easy to see why that should have occurred.

In conclusion, I would like to give the following extract from Tait's preface to the third edition of his "Quaternions".

"With regard to the future of Quaternions, I will merely quote a few words of a letter I received long ago from Hamilton:—'*Could* anything be simpler or more satisfactory? Don't you *feel*, as well as think, that we are on the *right track*, and shall be *thanked* hereafter? Never mind when.' The special form of thanks which would have been most grateful to a man like Hamilton is to be shown by practical developments of his magnificent idea. The award of this form of thanks will, I hope, not be long delayed."

Now Whittaker, heralding the dawn of that day, half a century after Tait gave that quotation from Hamilton, has given both Tait and Hamilton the needed thanks.

W. Peddie.

SOCIETY OF AGRICULTURAL BACTERIOLOGISTS

THE Society of Agricultural Bacteriologists shows each year a fresh increment of growth. This is partly due to the increasing attention which is being given to the study of bacteriology in relation to agriculture and partly to a gradual change in the composition of the Society. For some years it has been attracting a steadily increasing number of bacteriologists working in university departments and research establishments of various types, and in industries other than agriculture. Indeed, all the main branches of bacteriology outside the medical field are now represented among the members. The present policy of the Society is, by opening its membership to bacteriologists in different fields and by making contact with other societies and groups interested in the study of microbiology, to assist in the evolution of an association which will represent all the various branches of bacteriology in Great Britain.

The annual conference of the Society was held this year at Leeds during September 8–10. The majority of the papers were concerned with problems associated with the dairy industry, but several other aspects of bacteriology were represented.

The chlorination of sewage and sewage effluents, a practice which may be desirable in special cases of sewage disposal, was the subject of a paper which described the principles involved and gave the results of experiments showing the effect of chlorination on the bacterial population.

Interest in sandbags has led to the development of an accelerated test for textile preservatives. Pieces of treated and untreated fabric are fixed on aluminium frames and partially buried in containers filled with soil; the soil is held at 30° C. and at a constant moisture content so that cellulose-decomposing organisms may become active, and the strength of the samples is tested weekly.

A paper on the *Bacillus subtilis* group in relation to industrial products dealt with the activities of *B. subtilis* (an organism which is frequently identified as *B. mesentericus* or *B. vulgatus*) and of *B. licheniformis* in dairy products, canned foods, bread, sugar juices and other materials. Factors determining the occurrence of the organisms and controlling their growth were described.

A contribution dealing with the bacteriology of potato silage reported that no evidence could be obtained that any of the lactic acid bacteria survive the cooking of the potatoes. It appears that in practice the lactic acid fermentation, on which preservation depends, is due to accidental contamination. Excellent results have been secured by inoculating the cooked tubers with a combination of *Streptococcus lactis* and *Lactobacillus plantarum*.

A study of 'slowness' in cheesemaking has shown that certain cases are due to the occurrence in some milk of a streptococcus which produces a toxin inhibitory to the organisms of the starter. This example of bacterial antagonism was originally described in New Zealand and has now been observed frequently in Britain. The trouble is encountered most commonly when cheese is made from pasteurized milk; if raw milk is used the organisms which it contains can assume the functions of the starter.

Recent work on the pasteurization of milk has thrown new light on the effect of the process on the bacteria of raw milk, and the problem of the keeping quality of the product has thereby become clearer. The organisms which tolerate the treatment are corynebacteria, streptococci (chiefly *S. bovis* and *S. thermophilus*), micrococci and in certain samples aerobic spore-forming bacilli. Other bacteria are only rarely detected if recontamination does not occur. One paper reported the finding in 4 per cent of supplies of heat-resistant coliform organisms; the infection was traced to incompletely sterilized milking machines. There was some discussion of the bacteriological control of pasteurized milk, a subject which presents several difficulties owing to the conflicting results furnished by different methods. It was clearly brought out that the corynebacteria and many of the micrococci which survive pasteurization are unable to proliferate at 37° C., and their presence in pasteurized milk escapes detection by the plating method unless a lower incubation temperature is used.

Problems incidental to the condensing and drying of milk were discussed. Work on the bacteriology of dried milk powder and whey led to the suggestion that, as an interim standard, the plate count of a good quality roller-dried product, made within fourteen days of manufacture, should not exceed 5,000 per gm.

'Sterilized' milk, which is consumed in considerable quantities in certain parts of England, is not always sterile, and the findings of an investigation of this product were reported. The most important type of deterioration was found to be sweet curdling by spore-forming aerobes such as *Bacillus cereus* and *B. subtilis*. The trouble could not be related to the quality of the original milk or to the severity of the heat treatment, which varies from 30 min. at 218° F. to 1½ hr. at 225° F. in different plants, or to the efficiency with which bottles are sealed. Evidence was obtained that infection originates from inadequately sterilized plant and bottles, and that the organisms secure sufficient oxygen in a properly sealed bottle to allow of their multiplication. Abnormal flavours unaccompanied by visible changes in the milk were found to be produced by *B. thermoacidurans* and *B. circulans*, which may also be introduced from dairy equipment. Other papers dealt with sterilization in dairy practice and with bacteriological standards to be used in estimating the efficiency of the processes.

A case of 'ropy' milk due to a slime-forming coccus has been traced to infection from hay. A survey of samples of new hay showed that dust derived from this material may be a source of several species of bacteria which give rise to the abnormality. Coliform organisms isolated from hay were incapable of producing a slimy condition in milk.

Methods for the examination of milk continue to receive much attention. A recent innovation is the use of electrical methods for the rapid recognition of unsatisfactory milk. Souring is detected by a pH measurement, and mastitis milk, which is alkaline but has a high chloride content, is identified by means of a conductivity tester. Several papers were devoted to the methylene blue and resazurin reduction tests. The reduction of resazurin in pasteurized milk has been found to be unrelated to the plate count of bacteria which survive the heating. On the other hand, if milk shows rapid reduction in the raw state it behaves in the same way after pasteurization, thus suggesting that reducing substances resulting from bacterial activity in the raw milk are an important factor in post-pasteurization resazurin

tests. In the grading of raw milk a considerable proportion of samples are classified differently by the methylene blue test prescribed by the Ministry of Health and the routine resazurin test adopted provisionally by the Ministry of Agriculture, and further work on this problem is necessary. The complete reduction of resazurin has been shown to be generally slower than that of methylene blue in poor quality milk, but in the majority of samples with a good keeping quality it is similar or quicker. A study of the influence on dye tests of cells from the cow's udder has indicated that the amount of winter market milk which is reduced in grade owing to mastitis and late lactation is 4 per cent when the methylene blue test is used and about 10 per cent when the standard resazurin test is employed.

One of the papers on mastitis of the cow suggested the use of the Hotis test in routine laboratory diagnosis. After twenty hours incubation any samples which give a positive reaction are plated. This method, which economizes materials and labour, appears to be equal in reliability to direct plating.

A paper on the bacteriological aspects of blood transfusion discussed problems arising in the storage of blood and the production of plasma, and described methods of ensuring freedom from contaminating organisms. An account was given of the contaminants encountered in practice and of their action on blood and plasma.

The subjects discussed at this meeting of the Society show that problems in applied bacteriology which are largely related to war-time conditions are occupying the attention of the members. The dominant interest is in dairying, an indication of the national importance of milk and its products.

Copies of the Society's *Proceedings* containing the full papers can be purchased from the Hon. Treasurer, L. J. Meanwell, United Dairies, Ltd., Ellesmere, Salop.

MEASUREMENT OF HEARING AND DEAFNESS

AN article by M. B. Gardner (*Bell Lab. Rec.*, 22, No. 1; September, 1943) gives the results of tests carried out to determine hearing ability. Audiometers for measuring hearing loss vary considerably in arrangement, depending on how they are to be used and on how extensive a test is to be made. One of the models which has been widely used is the 2*A* audiometer manufactured by the Western Electric Company. It includes an adjustable oscillator as a source of single-frequency tones and an attenuator by which the intensity level of the tone may be varied. The person whose hearing is being tested listens to the tone through a small receiver, and is given a push-button with which he lights or extinguishes a lamp in front of the operator. Normal procedure is to have the lamp lighted as long as the tone is heard, and the patient extinguishes the lamp by releasing the push-button when the tone disappears.

Eight frequencies are provided from 64 to 8,192 cycles, which covers the important range of hearing, and the frequencies are selected as desired by keys on the audiometer. The output circuits for the various frequencies are so arranged that with the attenuator dial set to the point marked zero loss, the output of the receiver is at an intensity corresponding to the threshold of the average ear for that frequency. At this position of the dial the attenuator is inserting nearly its maximum loss—a small amount of additional loss being provided to enable measurements to be made on those who hear somewhat better than the average. The dial is graduated in 5db. steps. Normal procedure is to set the dial at a level that the patient can certainly hear, and then to reduce it step by step until the tone is no longer audible. The reading of the dial at the last step the patient hears gives his hearing loss at that frequency.

The intensities corresponding to the zero settings of the 2*A* audiometer, which represent the threshold of hearing for audiometric purposes, were obtained from tests on a group of people of normal hearing between the ages of twenty and thirty. They are on the average 10–15db. higher than the minimum audible pressure values given in an earlier article*. The objective of these values was to determine the minimum pressures that can be heard by the human ear, rather than the pressures heard under normal conditions by a more average group of people. That the values used by the 2*A* audiometer are well suited to their purpose is indicated by results obtained at the World's Fair in 1939. The threshold values of the 2*A* audiometer correspond very closely to those found during this survey.

Although the threshold curve is of fundamental importance in all acoustical work, there is another curve that is of interest, and that at times becomes of critical importance. As the level of a sound is increased above the threshold, the sound becomes louder and louder until the response becomes more that of the sense of feeling. The stimulus is felt rather than heard, and at somewhat higher levels becomes painful. A curve drawn through these pressures, at which the response is one of feeling as well as hearing, gives the so-called threshold of feeling, and marks an upper limit to audible pressures. The area between these two thresholds represents the range of audible sound pressures, and by plotting the results of audiometer measurements on such a field, it is possible to gauge at a glance the relative seriousness of any particular pattern of hearing loss. Charts indicating these two thresholds are usually employed when plotting hearing losses but, on them, the threshold of hearing is represented by a horizontal line near the top, and the threshold of feeling is plotted in decibels relative to the threshold of hearing.

Deafness may be due either to a transmission loss in the three bones of the middle ear, or to a reduced response of the auditory nerves. The former is called 'conductive deafness', and the latter 'nerve deafness'. With nerve deafness the loss usually increases at the higher frequencies. With conductive deafness, on the other hand, the loss is more constant with frequency, and may even be less at the higher frequencies. In addition, both forms of loss may be present, giving what is called mixed deafness. Even when it is not clear from the audiogram which form of deafness is predominant, the two types of deafness may be distinguished by other criteria. As a result of the lack of sensitiveness of the responding system that results from nerve deafness, no response is obtained until the stimulus reaches a certain value. Beyond this value, however, the response increases rapidly with the stimulus; so rapidly, in fact, that at high intensity levels individuals having one normal ear and one nerve-deafened ear judge the sound to be equally loud in either ear. With conductive deafness all sounds, of whatever level, suffer the same loss. The deafened person therefore hears more nearly

Bell Lab. Rec., 21, No. 10 (1943); see NATURE, 152 (Oct. 16, 1943).

like the normal individual, except that all sounds are reduced in intensity. Such an individual is not nearly so apt to complain of someone shouting too loudly as would the individual who has become affected by nerve deafness.

Those tested were asked to indicate their hearing ability according to five classes: (1) no noticeable difficulty in hearing; (2) unable to understand speech in public places such as churches or theatres; (3) unable to understand speech from a person two or three feet away; (4) unable to understand speech from a telephone; and (5) unable to understand speech under any condition. Their audiograms were then taken and recorded. Such tests were made on some 9,000 persons, and the audiograms of those of each of the five classes were then averaged to discover the amount and type of loss that was responsible for the various inabilities to hear. These results show, in a graph, that the five classes of loss are separated on the average by about 20 db. For those reporting normal hearing, the average loss was about 5 db., while for the other four classes it was 25, 45, 65, and 85 db., respectively, the latter figure corresponding to total deafness for speech.

STATISTICAL METHODS FOR GOVERNMENT DEPARTMENTS

THE "Memorandum on Official Statistics" issued by the Council of the Royal Statistical Society is a notable document, not merely for its recommendations for the post-war period, but also for the lucid and concise analysis of the pre-war period and the developments in war-time. The analysis of the pre-war period reflects little credit on the organization and method of the Civil Service. Each department collected its own statistics, and inadequate use was made even of the information available. The utilization of statistical material was imperfect and unsystematic, with loss of information and efficiency. No attempt was made to correlate the information with material available in other branches or departments. In only a few of the major departments was there any statistical organization which could be regarded as adequate. The staffing of departments was unsatisfactory in regard to the training of personnel and in certain respects to their status. Nowhere was a knowledge of statistical theory regarded as a necessary qualification for employment in statistical work, and the technical post of 'statistician' was practically unrecognized.

While the committee of the Royal Statistical Society which prepared the Memorandum is of opinion that in the pre-war period a good deal more could have been done by way of the analysis and interpretation of existing material, with great benefit to departments and to Ministers, it recommends that the collection of statistical material should continue, where possible, to be left to those departments and their branches the administrative duties of which bring them into daily contact with persons providing the information, so as to utilize the fund of experience acquired by administrative branches and the friendly relations which many of them have built up with their clientele. The branches may require advice from a co-ordinating statistical branch in the formulation of inquiries and the treatment of results, but the Memorandum is emphatic that the Central Statistical Office which is proposed to effect firm co-ordination of the statistical work of different departments should not relieve departments of their responsibility for collecting and compiling statistical data. Divorced so far as possible from routine analysis and from administration, it should be charged with the duty of preparing statistics required by the Government, such as the Budget White Paper, by Royal Commissions and by special committees appointed by the Government. It should ensure that as much statistical material as possible is made available to the public, and that all Government statistics are issued with the minimum of delay. It should endeavour to fill gaps in statistical information by advising departments on the desirability of certain lines of inquiry and should undertake research work or loan staff to assist other departments in undertaking such work.

Acting generally as a co-ordinating body, particularly through a small committee selected from the heads of statistical branches in the major departments, the Central Statistical Office should be responsible for the issue of the Statistical Abstracts for the United Kingdom and the "Guide to Current Official Statistics". It is suggested that the Office should also be responsible for the publication of a monthly bulletin of statistics on the lines of the Survey of Current Business issued by the United States Department of Commerce.

These are the principles on which the Memorandum considers the Central Statistical Office set up in 1941 should be reorganized after the War. The effect of the War has in fact been almost universally beneficial to statistics. The shortage of trained statisticians emphasizes the importance of the contribution they can make to the service of the State in the field of both descriptive and mathematical statistics. Some degree of internal training of the employees of statistical branches has been initiated, and increased use is being made of scientific aids to numerical work. There are also signs of a considerable change for the better in the public and departmental attitude towards statistics.

On the fundamental assumption that plans for reconstruction and for social reform will involve an increasing demand for comprehensive statistical information by the Government during the post-war reconstruction period and beyond, the Memorandum makes further recommendations. First, every major department should have a statistical branch under the direction of an administrative officer, and minor departments should either have a smaller unit or work under the guidance of the statistical branch in a major department or of the Central Statistical Office. Next, in regard to staff, certain statistical posts should be of grades equivalent to that of the more senior administrative officers, and the administrative personnel of statistical branches should be recruited from persons with mathematical or statistical qualifications; transfer between departments should be permitted where necessary. An endeavour should be made to post selected junior administrative officers to the statistical branch as part of their training, and technical posts of statistician created where departments consider them necessary. Full opportunity should be given for a technical statistician who showed administrative ability to be transferred to the administrative grade. The system of giving free courses in statistics to selected members of statistical branches should be extended and facilities given for advanced study. Opportunity should be given for members of statistical

branches to become familiar with the practical aspects of the matters with the statistics of which they are dealing.

The Memorandum also recommends transfer of personnel from departments to the Central Office and vice versa and, as already indicated, the staff of the latter should be available for assisting departments. The needs of certain departments for casual assistance should be met by providing the services of a mathematical statistician either by the appointment of a full-time officer, the loan of a suitable officer from the Central Statistical Office or the Department of Scientific and Industrial Research, the use of an advisory panel of experts, or by temporary engagement of a man from industry. The Memorandum particularly welcomes the interchange of expert personnel between industry and the Civil Service, and finally it is recommended that the Central Statistical Office or some other Government organization should ensure that the most effective use is made of modern machine methods.

The position of the Foreign and Colonial Offices, the Dominions Office and the India Office requires special consideration. In the Colonial Office at least, a statistical branch is recommended; but the responsibility for co-ordinating the trade statistics of the various Colonies should remain with the Board of Trade in view of the Board's experience in dealing with all trade statistics.

These proposals are parallel with those advanced on behalf of scientific workers generally, and which have commanded powerful support in recent reports and in debates in the House of Lords. The Memorandum is also in line with recent suggestions for Civil Service reform, including the training and recruitment of staff. Pronouncements of members of the Government in regard to the importance of statistics and the remedying of admitted defects in the existing service warrant the hope that this notable technical contribution to the improvement of the machinery of government will receive the official recognition that it well deserves.

A GAS-TUBE HARMONIC GENERATOR

IN a search for methods of obtaining currents of high and closely controlled frequency for carrier systems, the Bell Laboratories recently investigated the harmonics generated by triggering gas-filled tubes. The studies showed that gas tubes can produce much higher frequencies than had been thought possible, if operated in a new circuit which accelerates the ionization and de-ionization of the tube. The harmonics thus generated provide standard frequencies so high as 25 mc. for calibrating oscillators. The sharp current pulses are useful in testing television systems, for making phase distortion measurements in co-axial cables, and in high-speed triggering devices.

A typical gas tube with grid control is a triode filled at low pressure with mercury vapour or argon gas. If the grid is maintained at a constant negative potential with reference to the hot cathode while the plate potential is increased with reference to the cathode, only a very minute electron current passes to the plate until a critical plate-cathode potential is reached. This critical potential depends on the structure of the tube, the gas used and the magnitude of the grid potential as well as on the past history of the tube. When the critical potential is reached, an arc forms and the tube current suddenly rises. The voltage across the tube simultaneously decreases if an external load is connected in series with the source, and the tube continues to conduct until the plate voltage falls below a minimum value necessary to maintain the arc. When the arc is extinguished, the gas ions in the tube migrate to the tube elements and the tube finally becomes de-ionized. As the tube becomes de-ionized, the grid again regains control and the above process may be repeated. The time required for de-ionization determines the frequency at which the foregoing cycle may be carried out.

In the new harmonic generator circuit, the grid and plate are both supplied from the same A.C. source. This makes the plate voltage not only decrease to the value required to extinguish the tube, but also continue to a negative value. Likewise the grid voltage becomes negative. The negative potentials, primarily that on the grid, sweep the gas ions quickly from the tube, thus increasing the rate of de-ionization and the maximum frequency at which the tube can operate. An article by L. G. Kerota (*Bell. Lab. Rec.*, 22, No. 2; October 1943) describes the new circuit, its operation and performance.

In one practical application the gas-tube harmonic generator is used to test the fidelity of television-receiving equipment. Because it generates sharp wave fronts of controllable duration, black-to-white signal changes of great rapidity can be obtained. For determining the phase shift of signals in co-axial cables, two gas-tube circuits operate synchronously. Signals from one are used locally, and those from the other are transmitted over a looped line. The phase shift is determined by observing the difference between the wave fronts of the two pulses.

BIOLOGICAL RESULTS OF THE LAST CRUISE OF THE *CARNEGIE**

THE present publication, the sixth of the series and the fourth devoted to biological reports, includes accounts of the phytoplankton by Herbert W. Graham, the marine algæ by William Albert Setchell, polychætous annelids by Aaron L. Treadwell, the mysids by W. M. Tattersall and, in addition, several smaller papers in various groups.

The phytoplankton samples, chiefly from the open ocean, were taken at the surface, 50 m. and 100 m., and collected by the Petterssen plankton pump. The main contents were diatoms and dinoflagellates. The area investigated is here divided for convenience into three regions: the southern region in the south-eastern Pacific between South America and longitude 120° W., the tropical region extending from Panama and Peru as far west as Guan, and the northern region between Yokohama and San Francisco. All were poor in phytoplankton. In general, the richest samples occurred in water of low temperature, lower salinity, lower pH and higher phosphate content, whereas little correlation could be found between numbers of plant cells and percentage saturation of oxygen, or between number of plant cells and quantity of dissolved silicate. An interesting condition

* Scientific Results of Cruise VII of the *Carnegie* during 1928–29 under Command of Captain J. P. Ault. Biology, IV. Department of Terrestrial Magnetism. (Pub. 555.) Pp. vi+92. (Washington, D.C.: Carnegie Institution of Washington, 1943.)

was found in the northern region, where all but two samples showed supersaturation in the upper 100 m., the diatom and dinoflagellate populations being very low. This is probably to be explained by the presence of minute photosynthetic organisms not captured in the ordinary filter net.

The mysid collection, described by the late Prof. Tattersall, although not rich in species or individuals (with the exception of *Sirella thompsoni*), is of interest in containing rare and new forms, and the geographical range of those already known has been extended. Two are new to science. One of them represents a new genus named Carnegieomysis, only one specimen of which was obtained; it is a curious and anomalous mysid the affinities of which are obscure until the male can be examined. The eyes are peculiar and of a unique character, resembling those of certain euphausians, having the cornea divided into distinct dorsal and ventral parts. In this case, however, the two parts are separated by a groove in which the corneal elements are absent. It is a type of eye which is developed in response to a pelagic habit of life. Apart from the eyes, the most outstanding characters are the form and size of the antennal scales and the shape and armature of the telson.

Shorter papers report on the isopods, halobates, birds, a sponge, echinoderms, insects and mites, pyrosomids and a lizard.

FORTHCOMING EVENTS

Saturday, January 15

QUEKETT MICROSCOPICAL CLUB (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Inaugural meeting at the new meeting rooms, Sir Henry Dale, Pres.R.S., in the chair: Address by Mr. W. E. Watson-Baker, President of the Quekett Club; Special exhibition of members' work.

SHEFFIELD METALLURGICAL ASSOCIATION (at 198 West Street, Sheffield 1), at 2.30 p.m.—Annual General Meeting. Presidential Address.

Monday, January 17

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 3 p.m.—Mr. J. N. L. Baker and Mr. E. W. Gilbert: "The Doctrine of an Axial Belt of Industry in England."

INSTITUTION OF ELECTRICAL ENGINEERS (LONDON STUDENTS' SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 7 p.m.—Problems Night.

Tuesday, January 18

EUGENICS SOCIETY (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Debate: "That the Programme of Social Security set out in the Beveridge Report should be Supported on Eugenic Grounds".

INSTITUTION OF ELECTRICAL ENGINEERS (WIRELESS SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Discussion on "Comparative Merits of Different Types of Directive Aerials for Communications" (to be opened by Mr. J. A. Smale).

Wednesday, January 19

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. Henry Berry: "London's Water Supply".

INSTITUTE OF FUEL (at the James Watt Memorial Institute, Great Charles Street, Birmingham), at 2.30 p.m.—Mr. R. Whitfield: "Fuel and Metallurgical Furnaces".

GEOLOGICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 3 p.m.—Dr. E. B. Bailey, F.R.S.: "Tertiary Igneous Tectonics of Rhum (Inner Hebrides)".

ROYAL METEOROLOGICAL SOCIETY (at 49 Cromwell Road, South Kensington, London, S.W.7), at 4.30 p.m.—Annual General Meeting. Prof. D. Brunt, F.R.S.: "Progress in Meteorology".

Thursday, January 20

CHEMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Dr. H. W. Thompson: "The Scope and Limitations of Infra-Red Measurements in Chemistry" (Tilden Lecture).

Friday, January 21

INSTITUTE OF FUEL (at the Royal Technical College, Glasgow), at 5.45 p.m.—Dr. E. W. Smith: "Education in the Fuel Industries".

Saturday, January 22

BIOCHEMICAL SOCIETY (at the British Postgraduate Medical School, Ducane Road, Shepherds Bush, London, W.12), at 11.15 a.m.

INSTITUTE OF PHYSICS (ELECTRONICS GROUP) (joint meeting with the Midland Branch of the Institute of Physics) (at the University, Edmund Street, Birmingham), at 2.30 p.m.—Discussion on "Space-Charge and Noise in Radio Valves" (to be opened by Dr. P. B. Moon and Dr. R. R. Nimmo).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ASSISTANT MASTERS for (*a*) CHEMISTRY AND MATHEMATICS, and (*b*) PHYSICS AND GEOGRAPHY, at the East Ham Technical College—The Secretary for Education, Education Office, Town Hall Annexe, Barking Road, East Ham, London, E.6 (January 22).

PRINCIPAL of the Croydon Polytechnic and Evening Institutes—The Education Officer, Education Office, Katharine Street, Croydon (January 24).

LECTURER IN MECHANICAL ENGINEERING—The Principal, Derby Technical College, Normanton Road, Derby (January 24).

SPEECH THERAPIST (full-time)—The Director of Education, Leopold Street, Sheffield (January 25)

LECTURER (man or woman) IN ZOOLOGY—The Principal, Huddersfield Technical College, Huddersfield (January 31).

ENTOMOLOGIST in the Department of Agriculture, Salisbury, Southern Rhodesia—The Official Secretary, Office of the High Commissioner for Southern Rhodesia, 429 Strand, London, W.C.2 (January 31).

LECTURER IN PHYSICS—The School Secretary, St. Mary's Hospital Medical School, London, W.2 (February 1).

PRINCIPAL of the Gloucestershire College of Domestic Science and Training College—The Secretary, County Education Office, Shire Hall, Gloucester (February 5).

REGISTRAR—The Principal, University College of Wales, Aberystwyth (February 10).

CHAIR OF BOTANY tenable at King's College, and CHAIR OF BOTANY tenable at Birkbeck College—The Academic Registrar, University of London, c/o Richmond College, Richmond, Surrey (February 21).

LECTURER IN CHEMISTRY FOR MEDICAL STUDENTS—The Acting Secretary, University Court, Glasgow (February 25).

UNIVERSITY CHAIR OF ANATOMY tenable at St. Mary's Hospital Medical School—The Academic Registrar, University of London, c/o Richmond College, Richmond, Surrey (March 20).

TEMPORARY TECHNICAL ASSISTANT IN FARM ECONOMICS under the Department of Agriculture for Scotland—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. F.1944.A).

ASSISTANT ELECTRICAL ENGINEER for the Nigerian Government Public Works Department—The Secretary, Overseas Manpower Committee, Ministry of Labour and National Service, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. 538).

ELECTRICAL ENGINEER (temporary) for a Government Department at Bath, to deal with the design and installation of loud-speaker and broadcast systems—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. D.734.A).

ASSISTANT MASTERS for (*a*) GENERAL SCIENCE with MATHEMATICS, to take charge of laboratories, and (*b*) ENGINEERING SUBJECTS with MATHEMATICS in Day Technical School and Evening Institute—The Principal, Technical Institute, 28 Beckenham Road, Beckenham, Kent.

TWO SCIENCE TEACHERS, one a male teacher, main subject PHYSICS, with subsidiary Chemistry or Mathematics; the other, male or female teacher for GENERAL SCIENCE, with some Biological background—The Principal, Technical Institute, Rochester.

TWO (full-time) ASSISTANT TEACHERS for (*a*) SCIENCE and/or MATHEMATICS, and (*b*) GENERAL TECHNICAL SUBJECTS including Woodwork or Metalwork—The Principal, County Technical College, Stoke Park, Guildford, Surrey.

LECTURER (full-time) in MECHANICAL ENGINEERING to teach up to Higher National Certificate standard—The Principal, Wimbledon Technical College, Gladstone Road, London, S.W.19.

DEMONSTRATOR (full-time or part-time) IN PHYSICS—The Secretary, King's College of Household and Social Science, c/o University College, Leicester.

TRAINING AND RECRUITMENT FOR PUBLIC SERVICES

ALTHOUGH the appointment of Lord Woolton as Minister of Reconstruction is evidence of the importance which the Government now attaches to post-war reconstruction, it has raised afresh the whole question of the machinery of government. Just as in the four years 1914–18, the stress of war has brought to light the weaknesses of the peace-time machinery of government in Great Britain. Deficiencies at the policy-forming level, where the current purposes and objectives of government are thought out and harmonized, converted into definite policies, made administratively viable and translated into practical plans and directions for those who have to execute them, have been clearly revealed, and have sometimes formed the subject of constructive criticism, notably from the Select Committee on National Expenditure. Equally conspicuous have been the defects in the machinery for finding facts, for co-ordinating available knowledge and facts, and for drawing significant inferences from them.

The proposals for the reform of the Foreign Service laid before Parliament by Mr. Eden some time ago*, which have been so warmly welcomed, may undoubtedly be regarded as an attempt to remedy some of the defects from which Great Britain has suffered in the last two decades in one branch of government, in so far as the determination, co-ordination and interpretation of facts are concerned. It does not, of course, except indirectly, affect the policy-forming level in that field, which, as was emphasized by Mr. Law in presenting the proposals to the House of Commons, is not the responsibility of the Foreign Service, but of the Cabinet and ultimately of Parliament. That aspect of the question was well analysed by Political and Economic Planning (P E P) in Broadsheet No. 201, on "British Foreign Policy", issued a year ago. More recently, in Broadsheet No. 213, on "The Future of Foreign Publicity", P E P has returned to the information and fact-finding aspects, and detailed some further suggestions for implementing the foreign policy laid down by the Cabinet.

While the discussions at present proceeding about Government and industry and the maintenance of controls have equally tended to direct attention to the machinery of government, it cannot be said that fundamental questions have been explored quite so thoroughly. Certain suggestions have been advanced, for example, in the Nuffield College Statement "Employment Policy and Organization of Industry After the War" ; but on the other hand, while the question of the Civil Service itself has been thoroughly examined in a number of reports, even where the larger question of machinery of government is faced, as in the report of the Sub-Committee of the Liberal Party on Civil Service Reform, comment rarely goes further than the submission that the whole structure of government from Cabinet level downwards requires authoritative discussion. The reconsideration of the

*Cmd. 6420. (London : H.M. Stationery Office.) 2*d.* net.

present functions and machinery in the light of the principles laid down in the Haldane Report finds an increasing volume of support; what is required is not so much fresh inquiry as fundamental thinking on the application of the principles laid down in that report to the problems of government to-day.

Some such analysis was attempted by Political and Economic Planning in a broadsheet on the machinery of government which appeared in July 1941. That broadsheet was concerned with the adequacy of the Civil Service and with the reforms required to make it an effective instrument of government; its proposals found strong support in a subsequent report from the Select Committee on National Expenditure in the 1941–42 session, which may well take its place with the Haldane Report as a State paper of first-class importance. No less fundamental are the observations on the machinery of government in the fourteenth report of the Committee in the 1942–43 session. Political and Economic Planning has now carried its analysis a stage further in Broadsheet No. 214, on "A Civil General Staff", devoted particularly to the machinery required to facilitate the organization and co-ordination of national policies and their execution at a level intermediate between the Cabinet as a whole and the individual Minister.

This is the main problem which Lord Woolton has to face. Whereas at the Ministry of Food Lord Woolton's task was largely that of administering a defined and simple policy, with the advantage not only of a very competent higher staff but also that the field had been very thoroughly prepared before the War, the Ministry of Reconstruction is not primarily administrative. Lord Woolton's task is not to take the decisions himself, but to see that the right decisions of policy are taken without delay. It will require the statesman's vision to see problems in the dimensions of history, and the politician's art in getting things done. From Lord Woolton the task will demand boldness as well as vision; from the small but influential staff, on the model of that of the Ministry of Defence, rather than of the ordinary ministry, it calls for clear thinking.

However gifted a statesman Lord Woolton may prove to be, success in his present post will depend largely on how far the whole Government machine is attuned to meet the demands which the post-war period, as well as the transition from war to peace, will make upon it. Some attempt must be made to deal with the fact-finding machinery and with that for co-ordinating and timing policy so as to eliminate the more glaring defects. Some improvements have, in fact, recently been suggested in the memorandum on official statistics issued by the Council of the Royal Statistical Society (see NATURE, January 15, p. 88), which urges that the statistical units of Government departments should in future be staffed by trained men, the departmental units co-ordinated and the Central Statistical Office continued and developed. This important technical contribution to the improvement of the machinery of government is supported by the observations in the sixteenth report for the session 1942–43 of the Select Committee on National Expenditure, which lead to the recommendation that the provision of the full and informative records showing the extent and variety of State assets which the Government must have at its command to make decisions on policy concerning the disposal of such assets in post-war reconstruction, and the collection, classification and co-ordination of departmental inventories should be undertaken by some central agency.

These are matters of detail which may eliminate some of the creaking and facilitate the smooth running of the Government machine. They will not in themselves—though not entirely minor matters—obviate the need for creative thinking about the functions and organization of departments and their inter-relations so as to serve more effectively the needs of to-day. The main divisions suggested in the Haldane Report are not necessarily those which will best fit the post-war need; war-time needs have provided experience of the possibilities of regrouping ministries, and even introducing new ones, which at least require exploring. A Ministry of Industry, including the industrial branches of the Board of Trade and some sections of the Ministry of Production, leaving the Board of Trade to be concerned essentially with international problems, is one suggestion that has been advanced, while clearly the functions of the ministries concerned with housing and health require thinking out afresh in terms of the post-war pattern.

Whatever form such re-organization may take, its ultimate success will depend on the men and women who will be called upon to administer policy and execute decisions. It is almost universally admitted that this will involve the recruitment of new kinds of Civil servants. So far as the Foreign Service is concerned, that is implicit in the White Paper proposals and was stressed in the subsequent debate. More generally, it is required not because the Civil Service is inefficient or incompetent, but because the present Civil servants are brought up too narrowly to discharge expertly and with understanding the many new duties of control and oversight which have been forced by events upon the modern State.

That might fairly be described as the burden of the criticism in the House of Commons debate, and both the merging of the Foreign Office, the Consular, the Commercial Diplomatic and the Diplomatic Services into one Foreign Service and the measures proposed for widening the recruitment and training for the Foreign Service are designed to remove this acknowledged defect. Criticism of the proposal to supplement the preliminary competitive entrance examination by a method based mainly on selection, as voiced in the debate, was essentially constructive, though the examination system found staunch defenders, subject to special entry for exceptional and outstanding men only. Similarly, the proposed scheme of training in which the competitive examination is taken in two parts, the second following a period of training abroad, with subsequent training of the successful candidates for a year in Great Britain, partly in the Foreign Office and partly in getting a grounding in economic, commercial and social questions, was also very fairly considered with

the view of obtaining as representative recruitment as possible from all sections of society.

The importance of the general outlook and strata of the nation finding faithful reflexion in the Foreign Service, in order that the Service may be abreast of the current life and activities of the country and represent it abroad, was universally admitted, as well as the necessity of ensuring that the Service possesses the necessary qualities of personality and character as well as of intellect. It is the fusion of politics and economics in foreign affairs so strongly emphasized in a recent report of the Select Committee on National Expenditure to which Mr. Law referred, which has made it so much more difficult for the Foreign Service, as previously recruited, to fulfil adequately its double function: that of advising the Government and giving the Cabinet a background of information about foreign countries; and that of representing the Government and the country abroad, trying to execute the policy upon which the Cabinet is determined in those countries, and promoting British interests, of which international peace and understanding are the most important, within the limits set out by the Cabinet.

Mr. Law's speech did something to put criticism of the Foreign Office in its right perspective, but even those who paid tribute to the present system recognized that there have been occasions in recent years in which its information service appears to have been defective. Much that was said, however, on such matters in this debate was almost as relevant to the Civil Service as a whole as to what it is now proposed to constitute as a wholly independent Foreign Service. The Civil Service cannot be expected to function with full efficiency unless it is sufficiently representative and in touch with the temper and outlook of the whole nation.

Conversely, it must be remembered that the spirit and efficiency of the Civil Service, including the Foreign Service, reflect the temper and interest of the community it serves and from which it is drawn. No machinery will provide us with a Civil Service of the highest ability and integrity, imbued with vision, initiative and enthusiasm, unless the mutual understanding and respect between the Service and the community whose interests it serves and safeguards are such as to encourage recruits of the requisite standard to enter the Service. No matter what training is given to recruits after entry, the merits and defects of the educational system of the country as a whole are bound to affect the tone and standard of its public services.

Recognition of this truth has led the British Association Committee on Post-War University Education to give special consideration to education for the public services. A report on that subject has now been issued, in which are considered the relations between universities and government administration, including the question of graduate schools for future or existing Civil servants, combining university work with practical experience in government offices. Using the terms 'government administration' and 'Civil Service' in the broadest sense to cover the local government service, the colonial service, the public utility corporations and services involving international co-operation as well as the home and foreign branches of the Civil Service proper, the education of those intending to enter such services or indeed corresponding careers in large-scale enterprise is related to that of university studies in general discussed in the first interim report of the Committee. The necessity of adapting the curriculum to present-day needs and conditions, and the increasing danger to higher education involved in the growth of over-specialization in many branches of knowledge apply with as much force to those intending to enter any branch of the public services as to any other type of university student. Apart from this, it is urged that any broad discipline can be made to meet the needs of intending Civil servants, provided it is taught in such a way as to train students both to generalize from given data and to question or verify against experience the processes of their reasoning.

There are three distinct aspects of the problem: first, education before entry into the senior branch of service; second, provision for higher officials to renew contact with the university during their official life; and, third, opportunities for education of a higher type for officials of lower rank as a stimulus and as a means of attaining promotion. In regard to the first, the report makes some pertinent comments in regard to those intending to enter any of the careers which involve regular co-operation with foreigners, whether in the diplomatic services, in such work as that of the British Council, in official or unofficial international organizations, in business or in journalism. It is essential for those entering upon any form of foreign service to overcome our notorious embarrassment or inhibition in our relations with those whose background, outlook and language differ from our own.

The British Association Committee considers that there is scope for a form of education designed to facilitate the process of international co-operation, and the experience of the Geneva School of International Studies over the fifteen years 1924–39, is cited to show that this can be done with success in a carefully designed six weeks' course for a body of students not too large to form a single social unit. In such a school there is a double process of cross-fertilization between intellectual disciplines as well as between national outlooks, and this also is important. Some specialization is inevitable in the foreign services. Its proportion may well be diminished somewhat by Mr. Eden's reforms, but the number of specialists engaged may well be increased. Scientific workers, for example, will probably figure more prominently than hitherto in some aspects of international co-operation, as the experience of the War clearly shows; and they too should welcome the demonstration that there is a technique for at least facilitating international co-operation and acquiring the appropriate attitude of mind.

With regard to the second aspect of the problem, this report takes up the suggestion put forward by Mr. H. E. Dale in his book "The Higher Civil Service" of a period of long leave within a few years after entering the Service. This, it is suggested, would

usually be most profitably spent in attending an advanced course in social studies, especially in the atmosphere and surroundings of a college undertaking research as well as teaching. Further, most of the future members of the higher Civil Service should spend the six winter months of a sabbatical year, before the end of the first ten years of official life, in following one of these courses in a civil service college at a university, and devote the six summer months of this year to acquiring inside knowledge of the working of one or more foreign civil services or of the international secretariat of the League of Nations.

To provide for the third aspect of the problem, the Committee recommends the institution of courses of similar duration for members of the lower branches of the Civil Service. These would be designed to provide the substance of a university education for Civil servants of proved ability who have hitherto been denied one, and to open new avenues for their promotion; and the results of the examination at the end of the course would influence the prospects of the candidate. In this way it might well prove possible to tap fresh sources of ability which would enrich the public service out of all proportion to the difficulties and expense involved in working out the plan.

This report of the British Association Committee is supplemented by a memorandum on "American Education for the Public Services" by Mr. Willard Connely, which lays welcome stress on the importance of ethnographical study in international relations. While the report shows that there is still some confusion of opinion as to the functions and purpose of a staff college, it should stimulate further discussion on this important question of training and recruitment for the public services, and help to place it in a fitting perspective in the programme of educational reform to which the Government is now committed. That programme itself should help to throw up recruits of the requisite ability and character from ever-widening circles of society, and at the same time promote the harmonious and sympathetic relations between the official and those he serves, upon which as well as upon the training and integrity of the Civil servant himself the full efficiency of public administration always depends.

SCIENTIFIC ETHICAL PRINCIPLES

Evolutionary Ethics

By Prof. Julian S. Huxley. (The Romanes Lecture delivered in the Sheldonian Theatre, 11 June 1943.) Pp. 84. (London: Oxford University Press, 1943.) 2*s*. net.

A FEW weeks ago, at a session of the B.B.C. Brains Trust (at which Prof. Julian Huxley was not present), the opinion of the members was asked on a suitable ethical basis for modern thought and action. One member spoke up for orthodox Christianity, but, from the rest, there was complete silence. Much the same reaction would probably be obtained from any half-dozen people selected at random from the Western Democracies. Prof. Huxley, in his Romanes Lecture on "Evolutionary Ethics", sets out to fill this partial vacuum with an exposition of ethical principles and practice based on the scientific approach to life and its problems and, in particular, on the facts of evolution.

Ethics has three distinct, though interrelated, aspects, which may be epitomized in three questions: How do we come to make moral judgments at all? What reason, if any, have we for thinking that one judgment is right and another wrong? On what specific moral judgments ought we, in practice, to base our actions? The first is concerned with the developmental 'natural history' of ethics, the second with what Waddington has recently called "the age-long endeavour to find an intellectual basis for ethical judgements", and the third with practical or didactic ethics.

On the first question, Prof. Huxley expands the thesis, put forward earlier in his "Uniqueness of Man", of the evolutionary significance of the development in the human infant of what he calls the "proto-ethical mechanism". He accepts, broadly, the Freudian view that ethical judgments are a product of the child's conflict between its feelings of love for its mother as the provider of comfort and satisfaction, and its feelings of hate and aggression for that same mother as the authority which, frequently and necessarily, denies to the child the enjoyment of the comfort and satisfaction for which it longs. This conflict takes the form of 'all or nothing' alternations of love and hate, which persist, at varying levels of consciousness, into adult life, and, becoming transferred to such "objects" as sin, virtue, native land or racial group, constitute the raw material of adult ethical judgments. From an evolutionary point of view, why should such a mechanism, involving the complete suppression, at a given moment, of one or other of the opposing emotions, have been developed? Prof. Huxley interprets it as a device for securing "action rather than indecision in the face of conflict", and, as such, it clearly has survival value in the struggle for existence. In addition, however, the mechanism, by attaching a load of guilt to one of the conflicting impulses, weights the scales between them, and has the effect of securing one particular kind of action rather than another. In one of the many memorable phrases in his lecture, Prof. Huxley thus sums up the situation: "Primitive love conquers primitive hate by saddling it with the burden of primal guilt; and with this the polarity of right and wrong becomes attached to our thoughts and actions".

The child, then, enters on its passage to maturity equipped with this primitive and absolutist ethical mechanism, and the main problem confronting it is to adjust this mechanism to the facts of external reality by incorporating experience with the aid of reason.

The degree to which the mechanism does, in fact, become adjusted to reality varies enormously. In any society there are a number of individuals bearing a heavy burden of unrealistic guilt, while the ethical standards of all human groups are themselves more or less unrealistic. Nevertheless, in favourable circumstances, human beings *are* able to develop without such "overdoses of untruth and unreality in their moral system", and it is in the growth of an outlook preserving a balance between the emotional driving force of our infantile proto-ethics on one hand, and the guiding influence of ordered experience on the other, that Prof. Huxley sees the hope of ethical progress in the future.

This, very briefly, is Prof. Huxley's account of the 'natural history' of ethical judgment, and the mention

of ethical progress leads to the second question referred to above, the search for an objective criterion of ethical rightness and wrongness—a search which Wittgenstein once described as "a terrible business—just terrible! You can at best stammer when you talk of it."

For the solution of this "terrible business" Prof. Huxley looks to the concept of evolutionary progress, and the corner-stone of his thesis is that our ethical standards are not static but constantly evolving. "Our ethics," he says, "evolve because they are themselves part of the evolutionary process. And any standards of rightness or wrongness must in some way be related to the movement of that process through time." He goes on to define evolutionary progress as "the capacity to attain a higher degree of organization without closing the door to further advance", and points out that, with the advent, on the evolutionary stage, of human speech and conceptual thought, it became possible, for the first time, for one of the products of the evolutionary process, namely man, to take a conscious part in it and to inject into the hitherto blind and automatic mechanism the concept of moral purpose. This marriage of evolution and morals gives rise to three main principles of evolutionary ethics, namely, "that it is right to realize ever new possibilities in evolution, notably those which are valued for their own sake; that it is right both to respect human individuality and to encourage its fullest development; that it is right to construct a mechanism for further social evolution which shall satisfy these prior conditions as fully, efficiently, and as rapidly as possible". Prof. Huxley then goes on to show how these broad principles can be applied to a number of current and recurrent ethical and social questions.

This picture of moral purpose as part and parcel of evolutionary progress, and the programme of social change derived from it, will undoubtedly provide a stimulating inspiration to progressive thinkers at the present time, but one is left with the question whether Wittgenstein's "terrible business"—an objective intellectual basis for ethics—has, in fact, been satisfactorily settled. Prof. Huxley lays great stress on the development of emotional experiences which have "inherent value" or which "are valued for their own sake", and such experiences form, in effect, the core of his theory of ethics, as indeed they must of any naturalistic ethical theory. Is the criterion of the value of these experiences an intellectual one? Surely, on final analysis, we must agree with Hume, that the assessment of such values is fundamentally dependent on the *emotional feelings* of individuals or groups of individuals, feelings of which we can approve or disapprove, the origin of which we can trace, but for which, from their very nature, we cannot find any intellectual justification. Is not Wittgenstein's "business" so "terrible" precisely because there does not exist any intellectual basis even to stammer about?

To take this view does not, however, detract from the great value of Prof. Huxley's essay as a synthesis of the scientific and ethical approaches to human problems. If moral truths are banners which inspire the emotions, rather than statements which satisfy the intellect, the Romanes Lecture for 1943 must be reckoned as a notable standard for rallying the forces at present struggling to find a basis for ethics in harmony with scientific thought and untinged with the tenets of revelationary religion.

TECHNIQUE OF BLOOD-GROUPING

The Determination of Blood Groups

Medical Research Council War Memorandum No. 9. Pp. 28. (London: H.M. Stationery Office, 1943.) 4*d*. net.

It is doubtless true that on the great majority of occasions blood-grouping can be carried out correctly in a high proportion of cases even when the simplest procedure is used by the relatively inexperienced. But when the consequences of a mistake may be disastrous, as in blood-transfusion, and it is essential to get very near the limit of complete accuracy, it is found, as is so often the case in tests of biological material, that this can only be done by elaborate and meticulous technique in the hands of well-trained and experienced workers.

The Blood Transfusion Research Committee of the Medical Research Council has produced an admirable memorandum on this subject. A particularly lucid account is given of the principles underlying correct grouping and of the various sources of error which have been revealed by the wide experience of many workers.

The procedure of choice is a tube method, the cells being tested for agglutinogens and the serum for agglutinins. Direct matching of the donor's cells against the recipient's serum is also carried out. Should time and the necessary glassware render the tube method impracticable, a tile method may be used. In this case it is recommended that undiluted blood should not be used except by workers with long experience of the method.

The methods advocated are described in full detail, and it is recommended that one or other should now be followed by all transfusion services, without the introduction of personal modifications by less experienced workers. As the membership of the Committee shows, these recommendations have the highest authority behind them. They will doubtless be universally adopted.

An interesting account is given of the *Rh* factor, of which so much has been heard lately. There are two ways in which *Rh*-negative persons may develop in their serum immune bodies capable of agglutinating the cells of *Rh*-positive donors. The first is their development by the *Rh*-negative mother carrying an *Rh*-positive fœtus—the cause of the great majority of cases of erythroblastosis fœtalis. The second is the response of an *Rh*-negative recipient to transfusion with *Rh*-positive blood. The ideal method of preventing trouble due to these causes would be the use of *Rh*-negative blood only for *Rh*-negative recipients. Under peace-time conditions this may become possible; it may be that in the future the standard blood for transfusion will be *Rh*-negative as well as of Group *O*. In war-time this is quite impracticable. The Committee makes, however, a series of recommendations which should greatly reduce the dangers.

The practical business of blood transfusion is, of course, all-important; but the records do provide in addition a by-product of great value in the field of pure genetics. In genetics it is difficult to draw a line between pure and applied research. Any animal or plant may on occasion provide material for fundamental work. Man furnishes such an opportunity in connexion with the blood-groups, for more is known about the geographical variations of the fre-

quencies of these genes than is known in the case of any other gene whatsoever. The enrolment in war-time of vast numbers of donors has produced a correspondingly great opportunity for the extension of knowledge. But it also increases the possibility of unreliable bodies of data. Mass grouping may, on occasion, be very inaccurate as, for example, when gross errors are made through such faults as the use of stale serum or infected cells. It is true that a small percentage of errors would not matter much from this point of view, so long as they were random. Often, however, they may not be random, in which case even a small proportion of wrong groupings might lead to erroneous conclusions. For example, in the British Isles, the population of which is serologically variable, variations in the frequency of gene A are of great interest, as shown by the work of the Galton Laboratory and its Serum Unit. If workers in one area, owing to a lack of the precautions described in the Medical Research Council memorandum, wrongly assign a number of A_2 and A_2B persons to groups O and B, while in a neighbouring area this source of error is absent, a false conclusion on geographical or racial variation might easily be drawn.

Bernstein's well-known test does to some extent provide a check; it can be discovered whether the observed group frequencies are in unreasonable proportion. But only one degree of freedom is available, so that a discrepancy is difficult to interpret. Furthermore, errors may cancel each other (as I found in one large body of material).

The Medical Research Council memorandum should lead to much improvement. It is true that the mass statistics will usually be obtained from the registration of donors, this being carried out at a time when cells alone can be tested. Nevertheless, gross errors and biased errors should be largely eliminated: a great gain in regard to this fleeting opportunity, automatically available during a war and at no other time.

J. A. FRASER ROBERTS.

STRUCTURE OF CLOUDS

Cloud Reading for Pilots

By A. C. Douglas. Pp. x+120. (London: John Murray, 1943.) 10s. net.

THIS excellently illustrated little book contains 164 photographs of clouds taken by the author, who is herself a pilot. The treatment of cumulus and altocumulus is especially good, and there are several series of photographs of the same cloud taken at short intervals, showing the changes in progress. The majority of the photographs are from the ground, but a few are from the air. Both the illustrations and the descriptive matter reveal a keen and intelligent observer.

The text contains a brief outline of the physical processes of cloud formation, and includes the usual text-book diagrams of ascending air at fronts. Actually these are highly simplified, and the real processes are still imperfectly understood, providing plenty of scope for future work, from the point of view both of meteorology and of aviation. The book contains some useful hints for pilots, but an attitude of caution should be adopted towards predictions deduced from cloud structures, since the actual sequences of events are extremely variable. Prof. Brunt, in his preface to the book, indicates how the pilot can co-operate with the meteorologist and help with his own observations.

There are no major errors, and though some statements are not quite accurate, very few of these refer directly to the clouds. Strictly speaking, altocumulus castellatus (p. 77) should refer to clouds above 8,000 ft., the lower type being stratocumulus castellatus. The roll type of cloud shown in Fig. 59 is not due to thermal convection. Emphasis is rightly laid on the importance of ice-crystals in anvils, and this also holds for altostratus and all clouds from which precipitation normally originates. The distant shower shown in Fig. 60, and the "virga" (precipitation below clouds) in Fig. 62 probably consisted of snow-flakes, which form threads much more clearly visible than those due to raindrops. Indeed the melting of snow-flakes may terminate the tufts of virga, though evaporation is more frequent. A nebulous or 'watery' sky is usually due to snow-flakes or small ice-crystals.

The book can be recommended to pilots, and meteorologists can study the photographs with advantage.

INSECTS OF MEDICAL IMPORTANCE

A Handbook for the Identification of Insects of Medical Importance

By Dr. John Smart; with Chapters on Fleas, by Dr. Karl Jordan, and on Arachnids, by R. J. Whittick. Pp. x+269+13 plates. (London: British Museum (Natural History), 1943.) 15s.

THE great importance of certain groups of insects and other arthropods as vectors of disease-producing organisms affecting man, is universally recognized. In this way the subject of medical entomology has come into being and it is one which displays continuous rapid growth.

With an insect believed to be implicated in disease transmission, the first requisite is to ascertain its name. Accurate identification is of paramount importance, since the behaviour of closely related species may be totally different and demand different repressive measures. In normal years, time and facilities are usually available for sending specimens to a central institution for naming by specialists. Under war conditions, however, such procedure becomes greatly interfered with and an undue amount of time lost before the desired information is obtained. Often the specimens and correspondence are liable to loss in transit and the whole matter has then to be reopened on a fresh basis. The present volume is intended to obviate these drawbacks by providing the means for the identification of any insect known to be of medical importance. It is concerned with all the Old World species that come under this category. An elementary knowledge of entomology is assumed, and users of the book will find, after some practice, very little difficulty in following the tables and descriptions. These, moreover, are accompanied by good clear illustrations, many of which are original.

The authors are to be commended on having written a reliable and up-to-date treatise well adapted in every way for the purpose it is intended to serve.

A. D. IMMS.

HUMAN BLOOD GROUPS

By J. F. LOUTIT

THE blood group of a person is dependent upon the presence in his erythrocytes of specific antigens. These antigens, most easily demonstrated by agglutination methods, are usually referred to as 'agglutinogens'. The corresponding antibodies, or agglutinins, may or may not be found naturally in human sera. If not found naturally, they may be produced by an immune response in suitable human or animal subjects after the injection of erythrocytes containing the appropriate antigen.

Academically, the blood groups are of importance in the elucidation of the antigenic structure of tissue cells. Application of this knowledge to blood transfusion therapy, to medico-legal problems concerning disputed paternity, blood stains, etc., and to anthropological and genetic research follows.

First, there is a genus specificity of blood. Thus the serum of human beings will agglutinate the erythrocytes of lower animals; likewise the serum of each genus of animal will agglutinate human erythrocytes and those of other animal genera.

Secondly, there is frequently a difference between the bloods of individuals belonging to the same species. Landsteiner[1] first demonstrated this in human beings. Our knowledge of human blood groups dates from this original observation.

Landsteiner and his pupils were able to divide human beings into four groups, the groups being dependent upon the presence in the red cells of either or both of two iso-agglutinogens A and B, or their absence. An international nomenclature has been adopted on this antigenic basis, and the groups are now designated AB, A, B and O (O signifying absence of both A and B). Naturally-occurring iso-agglutinins α (anti-A) and β (anti-B) are found in the sera according to Landsteiner's law: Those agglutinins, and only those, are present in the serum for which there is no corresponding agglutinogen in the red blood cells. The groups are thus AB (o), A (β), B (α) and O ($\alpha\beta$). Occasionally, however, defective groups are found, for example, A (o) or O (α). This is rare in adults, but not uncommon in infants.

Subdivision of two of the blood groups, A and AB, was made by von Dungern and Hirzfeld[2] in 1911. Serum from a group B person, absorbed with certain group A bloods, lost its power of agglutinating other samples of these bloods, but still agglutinated most other bloods of group A. This phenomenon is apparently due to the presence of two iso-agglutinins in group B sera (and group O sera), α which agglutinates all group A and AB erythrocytes, and α_1 which agglutinates most but not all A and AB red cells. The bloods agglutinated by α_1 are designated A_1 and A_1B: those agglutinated only by α are A_2 and A_2B. It has been suggested that the difference between A_1 and A_2 (and A_1B and A_2B) is merely quantitative. On the other hand, there is evidence of a qualitative difference in that individuals of groups A_2 and A_2B can be immunized against A_1 blood by repeated transfusions, or, in the case of women, by bearing a child whose blood contains the antigen A_1 (Wiener[3]). Group A bloods which react with the iso-agglutinin even more weakly than A_2 cells have been described and denoted as A_3 [4] and A_4 [5]. Sub-groups of the B agglutinogen have not been discovered. The iso-agglutinin α_1 can occur naturally in the sera of individuals of group A_2 and A_2B as well as those of group O and B. In the former cases it is usually active only in the cold below 37° C.

The agglutinogens A and B are inherited as mendelian dominants. Von Dungern and Hirzfeld[6], who first proved this, considered that the inheritance depended upon two independent pairs of allelomorphic genes. Bernstein[7] showed that this hypothesis did not fit the statistical findings, and suggested that inheritance depended upon three allelomorphic genes, A, B and R (or O). This theory is now generally accepted, with the rider that A_1, A_2, A_3 and A_4 form a series of allelomorphic genes which determine the A antigen.

Under von Dungern and Hirzfeld's theory, group O individuals would merely possess erythrocytes lacking A and B agglutinogens. With Bernstein's theory it might be expected that such cells would contain an agglutinogen "O". In point of fact, a water-soluble group-specific substance has been prepared from O cells (Hallauer[8]). Moreover, sera which will selectively agglutinate O cells are known (Schiff[9]). These anti-O sera are often designated as α_2 sera as they also agglutinate the majority of A_2 bloods, probably those of the heterozygous A_2O genotype. They occur in some natural animal sera (Schiff[9]), for example, bovine, some immune sera (Hooker and Anderson[10]) and as cold iso-agglutinins (Landsteiner and Levine[11]) in some group B, A_1 or A_1B human sera.

Agglutinable factors in human red cells, other than the agglutinogens A and B, have also been discovered. From certain immune rabbit sera, Landsteiner and Levine[12] obtained agglutinins for two factors which they called M and N. Human red cells can contain either or both of these agglutinogens (but *not* neither). Iso-agglutinins in human serum for M have been reported only in a very few instances, but no reliable report of an iso-agglutinin for N has appeared.

Friedenreich[13] has described a rare sub-group of N which has been termed N_2.

The M and N factors, as shown by Landsteiner and Levine[14], are inherited as mendelian dominants and their heredity depends upon a single pair of allelomorphic genes.

Other agglutinogens have also been reported from time to time. Of these the best-known is the factor P, which like the A substance probably represents a group of related agglutinogens[15]. The antibody can be obtained from normal and immune animal sera and occasionally in human sera (extra-agglutinin-1).

The group specific substances A and B have frequently been demonstrated in tissues other than erythrocytes (*cf.* Landsteiner and Levine[17]) by specific absorption and inhibition techniques. Schiff[18] extracted these substances in two forms, water-soluble and alcohol-soluble. Schiff[19] also found them in body fluids of certain subjects. Schiff and Sasaki[20] have called such people 'secretors': they have also found group O 'secretors'. The power of secretion is inherited as a mendelian dominant.

The M and N substances were for a long time thought to be confined to erythrocytes. They have lately been found in normal tissues by Kosjakov and Tribulev[21] and Boorman and Dodd[22], who also showed that the Rh substance (*vide infra*) was present in tissues. It would appear that M, N and Rh are relatively insoluble in water, as their presence in saliva is minimal.

The group specific antigens are, like other antigens, protein in nature. Haptenes derived from commercial pepsin, peptone, etc., however, have been

prepared which possess to a high degree the serological characteristics of the blood group *A* factor (Schiff and Weiler[23]) and the group *B* factor (Witebsky and Klendshoj[24]) without being themselves antigenic. They are polysaccharide complexes without protein. An artificial antigen of group *A* specificity has been prepared (Morgan[25]) by combining the *A* hapten with a protein.

Historically the latest and, from the transfusion therapy viewpoint, after *A* and *B* the most important blood group factor to be described, is *Rh*. It was first demonstrated (Landsteiner and Wiener[26]) by the use of an immune agglutinin produced in rabbits by injection of the blood of rhesus monkeys. The identity of this agglutinin with immune iso-agglutinins produced in man by repeated transfusions of blood of the correct *ABO* group[27] or by pregnancy[28,29] was soon demonstrated. In both instances persons whose erythrocytes lacked the *Rh* factor had been immunized by the *Rh* antigen. In the transfusion cases the blood transfused contained the *Rh* antigen in the erythrocytes; in the pregnancy cases it is necessary to postulate a leak of *Rh* antigen across the placental barrier from fœtus to mother.

In pregnancy, Levine, Katzin and Burnham[29] showed that this iso-immunization of the mother reflected on the newborn child, which manifested signs of 'erythroblastosis fœtalis' (hydrops fœtalis, icterus gravis neonatorum, congenital anæmia of the newborn). In view of the now accepted etiology of this condition, hæmolytic disease of the newborn is a preferable term. The immune iso-agglutinin passes back across the placenta and interacts with the fœtal erythrocytes and destroys them. Ottenberg[30] had previously suggested that this disease could be caused by iso-agglutinins α or β of the mother affecting her fœtus of group *A* or *B* respectively. The *ABO* blood groups, however, had no relation to the disease, and it is thought that the water-soluble group specific substances present in the body fluids of most *A* and *B* fœtuses would neutralize the offending agglutinin. Non-secretors would, on the other hand, be liable to be affected, and a few cases of hæmolytic disease of the newborn may be due to this cause. Immune iso-agglutinins, other than the typical *Rh*, could also produce it.

Suitable antibodies for the detection of the *Rh* factor are available by animal immunization—rabbit (Landsteiner and Wiener[26]) and guinea pig (Landsteiner and Wiener[31])—or they can be obtained from immunized human subjects. A special technique for their detection is required[32,33]. Different sera do not always give absolutely identical results, so for each *Rh* determination at least three sera should be used. In these circumstances it is found in the white populations of London[33] and New York[34] that approximately 85 per cent of persons are *Rh* positive and 15 per cent *Rh* negative.

It should be noted that, whereas 92 per cent of 153 mothers of infants with hæmolytic disease of the newborn were *Rh* negative (Levine, Burnham, Katzin and Vogel[35]), not all *Rh* negative mothers with *Rh* positive husbands (12 per cent of all matings) have affected infants. The *Rh* factor is inherited as a mendelian dominant (Landsteiner and Wiener[32]). If the father is heterozygous, *Rhrh*, half the offspring will be *Rh* negative and therefore unaffected. Even if the father be homozygous *RhRh*, although all the offspring will be *Rh* positive, one or more of the first children may be spared, because a greater degree of iso-immunizing stimulus may be necessary than is provided or the mother may be unduly resistant. In fact, it has been calculated (Javert[36]) that only 1 of every 438 newborn infants suffers from one or other form of the disease.

On the other hand, while 90 per cent approximately of mothers of infants with hæmolytic disease are *Rh* negative, the remainder are *Rh* positive. These subjects, like the *Rh* negative cases, show evidence of iso-immunization by their fœtus and provide interesting antibodies. One such antibody described by Levine, Javert and Katzin[37] and designated anti-*Hr* reacted mainly with *Rh* negative bloods, but also with some *Rh* positive bloods. A somewhat similar antibody has been denoted by Race and Taylor[38] as *St*. It agglutinated all *Rh* negative bloods and all heterozygous (*Rhrh*) bloods, but failed to agglutinate about 20 per cent of all bloods, and these must therefore be homozygous *RhRh*. Race, Taylor, Boorman and Dodd[39] report yet another antibody (*KJ*) which reacted with approximately 30 per cent of all bloods. This is similar to an antibody just reported by Wiener[40]. Race *et al.* suggest from the reactions of the *Rh*, *St* and *KJ* antibodies the probability of there being at least five allelomorphic genes: Rh_1, Rh_2, Rh_x, Rh_y and *rh*.

It will be remembered that not all anti-*Rh* sera give identical results. 84–85 per cent of positive reactions were obtained with standard animal serum (Landsteiner and Wiener[26]); 70 per cent with a human serum described by Wiener[28] and 86–87 per cent with most human sera (Levine *et al.*[35]). Wiener now calls the standard animal serum anti-*Rh*, the 70 percenter anti-Rh_1 and the 87 percenter anti-Rh'. This anti-Rh' is really a mixture of the two agglutinins anti-*Rh* and anti-Rh_1 and, by absorption with *Rh* positive bloods which do not react with anti-Rh_1 serum, the anti-Rh_1 agglutinin can be isolated. It was postulated (Wiener and Landsteiner[41]) that bloods which reacted with this anti-Rh_1 agglutinin belonged to type Rh_1, and those that reacted only with the standard guinea pig serum to type Rh_2. Up to this point, types Rh_1 and Rh_2 were analogous to group A_1 and A_2 bloods. Some rare bloods (Landsteiner and Wiener[32]), however, react with anti-Rh_1 (and therefore anti-Rh') but not with standard animal anti-*Rh*. The agglutinin, recently described by Wiener[40], reacting with 30–35 per cent of normal bloods, agglutinates bloods of so-called type Rh_2.

I have had the privilege of seeing a personal communication from Wiener, the manuscript of a paper to be published. The reactions of bloods to the agglutinins anti-*Rh*, anti-Rh_1, anti-Rh_2 and anti-Rh' are explained by postulating six allelic genes Rh_1, Rh_2, *Rh*, Rh', Rh'' and *rh*. Rh'' appears to be identical with the Rh_x of Race *et al.*, but Rh' appears to differ from Rh_y.

Race, Taylor, Cappell and McFarlane[42], by using an anti-Rh_1 serum in addition to anti-*Rh*, *St* and *KJ* sera, have confirmed the existence of the rare genes Rh' and *Rh* of Wiener, but suggest that the latter be termed Rh_0 as *Rh* has for so long had a wider meaning. The reactions of the various sera in identifying the genes can be best summarized as in the accompanying table.

By means of these four anti-sera, the genotypes of about 80 per cent of people can be determined if one ignores the rare genotypes. These latter can, however, often be detected by family studies.

The antibodies anti-Rh_1, *KJ* (anti-Rh_2), *St* and anti-*Rh* (animal) appear to be single antibodies and

Genes	Anti-sera			
	Rh	*St*	*KJ*	Rh_1
Rh_1	+	—	—	+
Rh_2	+	+	+	—
Rh_0	+	+	—	—
Rh'	—	—	—	+
Rh''	—	+	+	—
rh	—	+	—	—
Rh_y	?	—	+	?

not mixtures. It is tempting to postulate that these antibodies react specifically with partial antigens of the genes. Thus genes Rh_1, Rh_2 and Rh_0 would contain one common partial antigen; Rh_1 and Rh' another; Rh_2, Rh'' and Rh_y yet another; and Rh_2, Rh_0, Rh'' and rh a fourth. It is certain that the antibodies determine the presence of the genes wherever they occur: the various factors, therefore, appear to have equal dominance.

Although the final sorting out of the *Rh* complex and of the various anti-*Rh* agglutinins is not yet complete, it is clear that enormous strides have been made by increasing the identifiable types of human blood. Moreover, as stated by Wiener and Sonn[43], results appear to indicate that the *Rh* genes are located on a different pair of chromosomes from *ABO* genes. These in turn are located differently from *M* and *N* (Landsteiner and Levine[14]), so there are available at least four, including sex, of the twenty-four pairs of chromosomes for linkage studies in human genetics.

UNCONSIDERED TRIFLES IN OUR DIET

VITAMIN CONTENT OF BEVERAGES

By SIR J. C. DRUMMOND and DR. T. MORAN

IT will be of interest to students of nutrition to point out some of the important results that have been obtained during the past twelve months from a re-examination of the contribution made to the nutritive value of our diet by common foods that are often ignored when evaluations are being made.

One of us (T. M.), in collaboration with Dr. J. B. Hutchinson[1], pointed out that water drunk in one form or another can add substantially to the daily calcium intake. An approximate estimate of that provided by drinking-water alone over the country as a whole was 75 mgm. a day. In some areas where the water is 'hard', the figure would be much larger. A modest pint of beer daily can provide about 70 mgm. Such quantities should not be ignored in calculating calcium intakes. Widdowson and McCance[2] have also stressed the importance of calcium from such sources, and have shown that contact of food with iron utensils often materially raises the quantity of iron in the diet.

Consideration of beer led to a re-investigation of its vitamin content. Since the original study by Harden and Zilva[3,4], it has been widely assumed that beers consumed in Great Britain have a vitamin content that is negligible. In the Medical Research Council Special Report on Vitamins[5] published in 1932, there is, however, a reference to an unpublished observation by Aykroyd that stout contains what was then known as "vitamin B_2", but no further information about this has been traced. In view of the properties of riboflavin and nicotinic acid, as contrasted with those of B_1 which is readily adsorbed by yeast, it appeared reasonable to expect that beer would contain a high proportion of the amounts of these two substances contained in the malt. This has proved to be the case. Both in the laboratories of the Cereals Research Station of the Ministry of Food and in Prof. R. H. Hopkins's Department at the University of Birmingham, riboflavin values for beers ranging from 0·5 to 1·7 μgm./c.c. have been found[6,7].

The riboflavin content of beer appears to be related to the strength of the brew. Samples of malt that we have examined have given values of 5·6 μgm./gm. (as against 2·5 μgm./gm. for barley), and on the basis of one pound of barley yielding three and a half pints of beer (corresponding roughly to present-day beer) it would follow that complete extraction of the riboflavin from the malt would give a beer of approximately 1·3 μgm./c.c. Complete extraction is unlikely, but it indicates the limiting riboflavin content. On the other hand, a sample of strong ale as supplied to Queen's College, Oxford, before the War gave a riboflavin figure of 3·9 μgm./c.c. What promised to be an even more interesting ale—a brew of 1798 to celebrate the battle of the Nile, kindly supplied to us by Mr. Julian Baker—gave the disappointing figure of 0·8 μgm./c.c. Very probably there had been some destruction of the vitamin during the intervening 150 years.

In these examinations the riboflavin values were determined by the microbiological technique[8], but a biological test on a sample of beer sent to Miss Copping

of the Lister Institute has given the value of 0·7 μgm./gm., or identical with that obtained microbiologically.

Beer is a good source not only of riboflavin but also of nicotinic acid (of the order of 15 μgm./c.c.), and it is also a reasonable assumption that it contains appreciable amounts of other recently identified nutrients, such as biotin, pantothenic acid and inositol. As regards the latter, there is appreciable destruction of phytic acid during germination, with a corresponding increase in the amount of inositol present. Thus in a sample of malted English wheat the phytate phosphorus was found to be 190 mgm. per cent as against an average figure of 270 mgm. before germination. In passing, we cannot refrain from directing attention to these new aspects of the nutritional merits of that popular lunch—bread, cheese and beer.

Brewed vinegars are also of interest in this connexion, and in the case of riboflavin have been found to have a content of approximately 0·7 μgm./c.c. Artificial vinegars, as would be expected from their composition, contain no nutrient materials.

The riboflavin content of beer seems to provide part of the explanation of the relative rarity in Great Britain of clear-cut symptoms of deficiency conditions. This is in striking contrast to what is seen in the United States and Canada. When Dr. V. P. Sydenstricker, one of the leading authorities on riboflavin and other deficiency conditions, was in England a short time ago, he was greatly impressed by the contrast but he found it difficult to give a plausible explanation. Beer drinking does not provide a complete answer, because there is no evidence that abstainers show a high incidence of signs of riboflavin deficiency. When one of us (J. C. D.) was recently in Washington, Dr. W. H. Sebrell informed him that he had obtained evidence of the presence of appreciable amounts of riboflavin in tea. This has been followed up with the following results, obtained on a few samples.

	μgm. per gm.
Tea	9·0
Coffee	1·7
Cocoa	2·7

These figures indicate that an amount of the order of 10 μgm. of riboflavin might be provided by a breakfast cup of tea. The daily quantity would certainly not be negligible in the case of the habitual tea drinker.

Following the same line of reasoning that led to the re-examination of beer, it was thought desirable to analyse commercial meat extracts. For a long time these have been dismissed by nutrition experts as of little or no value as foods. Lean meat is, however, a good source of nicotinic acid and contains an appreciable amount of riboflavin. Consideration of the methods of manufacturing meat extracts suggests that there would be considerable leaching out of these vitamins into the extract. This appears to be the case, since five well-known proprietary brands of meat extract gave riboflavin and nicotinic acid values in the ranges of 15·4–25·8 and 410–1,025 μgm./gm. respectively. A breakfast cup of these extracts would provide on the average 0·2 mgm. of riboflavin and 7 mgm. nicotinic acid. These quantities are by no means insignificant.

It is possible that the relatively high nicotinic acid content of meat extracts may prove to be related to their reputation as stimulants. The recent work of Frankau[9] is of interest in this connexion.

The experimental results reported above are only preliminary, but they are clearly of importance not only in connexion with an accurate assessment of our overall intake of nutrients but also in indicating fruitful lines of research in malting and food processing generally. It is certain that in brewing research in the future, stress will be laid on the conditions of malting and mashing that will give the maximum production of vitamins consistent with other requirements in the brewing process. Malted cereals would indeed appear to be deserving of the most careful study. Malt extracts may appear in a new light. Examination of a random concentrated sample gave a value indicating a riboflavin content of 8 μgm. per gm.; the nicotinic acid content will be correspondingly high. Malt products may, therefore, be of considerable importance as ingredients in bread and such products as breakfast foods, chick foods, etc.

Meat extracts are only half the story of meat processing; any concentration of vitamins in extracts means a corresponding poverty in corned beef. Likewise the inclusion before the completion of the process of any material extracted in the preliminary treatment of meat before drying is desirable not only on grounds of palatability but also of nutritive value.

This communication refers mainly to work being carried out at the Cereals Research Station of the Ministry of Food, St. Albans, particularly by Drs. E. C. Barton-Wright and R. G. Booth. Full details of this work will shortly be published.

PRESERVATION OF FOODS BY DRYING

By DR FRANKLIN KIDD

Superintendent, Low Temperature Research Station, Cambridge

DRIED foods as a war development have been well advertised, particularly in the United States of America. With the exception of dried egg and dried skim milk ('household milk'), they have not, however, been on sale to the general public in Great Britain. The intelligent layman, therefore, in view of what he has been told through the Press about the exceptionally good quality of dried foods which modern science and technology have been able to achieve, although probably sceptical, would naturally like to try them.

An account appeared in NATURE of August 22, 1942, of a joint meeting of the Nutrition Society and of the Food Group of the Society of Chemical Industry at which the Department of Scientific and Industrial Research demonstrated the results achieved by British science during the War in improving the quality of dried foods. Dried vegetables—potato, cabbage, onions, swede—dried meat, dried egg, dried fish, dried milk and dried soups were served at lunch-time for appraisal by some hundreds of scientific and

technical workers present on that occasion. It was understood that the manufacture of products of corresponding quality was being actively developed.

Considerable interest is attached, therefore, to a recent lecture on the "Preservation of Foods by Drying" by Sir Joseph Barcroft, chairman of the Food Investigation Board of the Department of Scientific and Industrial Research, delivered at the Royal Institution on November 26.

Sir Joseph apologized at the outset for turning the lecture hall of the Royal Institution into something strongly resembling a kitchen, but aptly quoted from the original documents of the foundation, which described its objects as "for bettering the condition and increasing the comforts of the poor" by, among other things, "teaching . . . the application of science to the common purpose of life". There may be prejudice, he said, against dried foods. There is only one really adequate way to test dried foods, and that is to eat them. The *pièce de résistance* offered to the audience was a large shepherd's pie made on the demonstration bench from dried meat, dried potato, dried onion and dried milk, by Mrs. Edkins, reader in physiology in the University of London, and cooked during the lecture in Lady Dale's oven in the residency of the Director of the Institute. The audience accepted Sir Joseph's advice, and the observer records that nothing eventually remained but the dish.

In many instances acceptability to the palate has turned out to be a good criterion of nutritive value. In the case of milk and vegetables—and Sir Joseph thinks the same might be said of fish and meat—if the taste of the food is such as to make an appeal to the palate, the nutritive value of the food is largely unimpaired, and this to a physiologist with a nineteenth century background is not a little gratifying.

The drying of food aims at defeating both 'time' and 'space'. With regard to 'space', drying, combined with the process known as blocking, reduces the weight and volume of food to something like one eighth of the original. The actual reduction varies from food to food and is summarized in the accompanying table.

The same table shows how far drying combined with proper packaging and storage turns perishables into non-perishables, and so frees distribution from narrow and hampering time limits. But time is also defeated in another sense, that is, in the household, by the ready-to-eat or nearly ready-to-eat nature of the foods.

The world is shrinking. Each of us has less room and fewer hands at his disposal. Nowhere is this more important than in the kitchen. Silent forces are all the time impelling modern man to reduce his food,

Attainable saving calculated as between the most compact form and the form in which the commodity is most usually carried; and the *attainable storage time* after which the food is still in excellent condition, in gas-pack if necessary.

Food	Storage time	Saving per cent		Comparison with
		Weight	Bulk	
Meat	Indefinite	75	84	Frozen carcase, bone in
Fish	At least 1 year	90	85	Whole fish
Milk	Several years	87	89	Liquid milk
Egg	At least 1 year (temperature not higher than 60° F.)	80	90	Shell egg
Cabbage	2 years	95	87	Vegetables off farm
Potato	2 years	83	85	

while retaining to the full its palatability and nutritive value, to a form occupying the smallest possible space, having the least possible weight, keeping for the longest possible time and, above all, being as near as may be ready to serve and eat.

In the sense of being ready-to-eat and having a long storage-life dried foods are alternative to canned foods. With both, refrigeration is unnecessary. Canning has had most astonishing successes; it remains to be seen whether drying, under the acid test of use in war and afterwards in peace, will be able to emulate these successes.

During the lecture the following commodities were dealt with in turn, particular emphasis being placed on the properties enumerated above—retention of nutritive value and palatability, ease of preparation, saving in weight and space and storage life. The commodities were meat, fish, vegetables (various), eggs and milk. These commodities, with the exception of fish, are now all in production, specially tuned up in the light of recent discoveries, for the needs of the War. In all cases it was pointed out that drying as a process is nothing new to human art; what is new is the retention of quality: dried meat, among dried foods, is the latest arrival. Dried eggs, vegetables, and also dried milk have been known to commerce since the War of 1914–18.

Meat.—Fresh meat is cut into small pieces, and dried in a current of hot air, after being heated for a short time to 100° C. For the full flavour of the meat all the juices escaping in cooking must be returned prior to drying, and the temperature of the drying in warm air must be carefully controlled. These are the main provisos. The quality of the product afterwards reconstituted and cooked is little, if any, inferior to that of meat which has not been dried.

The product is a uniform one, and objective standards of quality can be set for various properties, flavour, consistency, nutritive value, fat content, freedom from bacterial contamination, etc.

Above all, dried meat, as to-day defined, is whole meat, nothing having been taken out in the process of preparation except water. The cooking is simply throwing the meat into hot water and cooking immediately, the time taken being that corresponding to the time taken for fresh meat. It is possible to make any dish which requires meat reduced to a mince or to small pieces.

Fish.—Fresh fish is dried in a very similar way to meat. In the case of fish, however, both the proteins and the fats are of a more delicate and labile nature. It had at first been thought that oily fish would present a difficult problem to the dehydrator, but experience has shown that this is not in fact so.

The flavour of fish is to some extent a post-mortem development. Sir Joseph described his experience at the Torry Research Station of the Department of Scientific and Industrial Research, of what he described as a spectrum of fish-cake flavours. Really fresh fish in many cases appears to have very little flavour at all. The fact that herring can be successfully dried may be of importance in the future to the herring industry.

Vegetables.—For drying of vegetables the principle of a pre-drying heat treatment is again used, the destruction of enzymes being of great importance. The savings in weight and bulk are usually most striking; for example, in the case of cabbage, weight off the farm 25lb., weight of dried material 1 lb. The demonstration exhibited a block of dried cabbage;

it was thrown into boiling water, swelled up and was completely cooked in twenty minutes.

There are special difficulties attached to the drying of potato which centre around the fact that the starch grains are gelatinized in the pre-drying heat treatment so that, if the cellulose cell wall enclosing them is broken, sticky consistency is produced on reconstitution with water.

On the subject of the retention of vitamins, particularly vitamin C in dried leafy vegetables, an experiment was quoted in which four hundred men were divided into two groups. Cabbage was served as part of a meal; one group had cabbage of good quality bought on the market and cooked in the ordinary way by professional cooks, the other group was given reconstituted dehydrated cabbage, prepared by the same cooks. In the result less cabbage was left on the plates of the latter group, and the intake vitamin value was higher in the case of the dried cabbage than in the case of the fresh cabbage.

Milk.—Milk has always presented a difficult problem of storage. The consumer has long known of sweetened condensed milk and unsweetened evaporated milk. In this case the weight of a quart is reduced from something like 41 oz. to 17 oz. When milk is dried the weight is further reduced to between 5 and 6 oz.

Dried milk can be made which on reconstitution is scarcely, if at all, distinguishable from fresh milk. Further, it can now be stored for periods of up to a year without noticeable change in palatability or nutritive value. Sir Joseph stressed the fact that Britain is a milk-producing country, and that one of our problems had always been that of dealing with the surplus spring and summer milk which is produced in the first flush of the growth of grass. He thinks it has now become possible for the consumer to use the excess of summer milk the following winter.

General Principles.—The general principles whereby high quality is obtained in the drying of food, and the relation between drying and preservation by cold storage in the frozen condition, were briefly sketched. A process of drying foods which has not yet been developed on the commercial scale was referred to, namely, that of evaporating the ice from frozen foods without thawing—the process which is, in fact, now being used for the storage of human plasma and sera for transfusion.

One of the main principles in successful drying is the destruction of enzyme systems by pre-heat treatment; the other is the protection of the dried products from atmospheric humidity and oxygen. Careful control of temperature is always necessary.

Blocking.—On the question of blocking, it was pointed out that in the case of meat the latest development, that is, blocking, has been adopted from the outset. Besides the further saving in volume, blocking has the effect of eliminating oxygen from the pack, which in the case of meat is a hermetically sealed tin. It retards penetration of oxygen if, as in the case of certain other foods, hermetically sealed cans are not used.

Blocks of carrot and cabbage were demonstrated, and it was understood that while most of the preliminary work and development has now been done, blocking has not yet been practised on a large commercial scale except in the case of meat. In the case of dried vegetables which pack very loosely, blocking effects a big further saving in volume.

In the course of his lecture Sir Joseph said that, while he has been for the most part presenting work carried out by the Department of Scientific and Industrial Research on the advice of the Food Investigation Board, and principally at the Low Temperature Research Station, Cambridge, he wanted to say that there has been fruitful and active collaboration both with the Agricultural Research Council and the Medical Research Council throughout. The Agricultural Research Council is especially concerned with milk, and the Medical Research Council with the retention of nutritive value.

In the case of all the newly developed foods of high quality, he stressed the fact that this quality is now scientifically ascertainable and statable in objective terms so that a definite standard could be set and insisted on, and the consumer, if necessary, could be protected against exploitation. The principal properties tested at present are palatability, nutritive value and storage life. New techniques are being worked out for assaying palatability. The great development during the last three years of spray-dried egg in the United States and Canada, due to their genius for mass production, has all been subjected to rigid quality tests based on the results of researches in which Great Britain had been to a considerable extent the pioneer.

OBITUARY

Sir Robert Alexander Falconer, K.C.M.G.

ON November 8, 1943, Sir Robert Falconer was buried from the Convocation Hall of the University of Toronto, over the destinies of which he had presided for twenty-five years. An attack of coronary thrombosis in 1930 impaired his health and compelled him to retire in 1932. His father, a Canadian of Scottish ancestry, was a Presbyterian missionary for some years in Trinidad. Here his son obtained his early education; and from the West Indies won a Gilchrist Scholarship which enabled him to attend the University of Edinburgh. In those days Butcher and Sellar lectured in classics; A. S. Pringle-Pattison in philosophy; David Masson in English literature; and Chrystal and P. G. Tait in mathematics and natural philosophy. Young Falconer graduated with honours in classics and philosophy, and proceeded to the study of theology in Edinburgh, Leipzig, Berlin (under Harnack) and Marburg. He returned to Canada to become at first professor of New Testament Greek, and then principal, of Pine Hill Theological College, Halifax, Nova Scotia. Here he remained until 1907.

In that year Falconer was chosen president of the University of Toronto, which had recently been reorganized by a Royal Commission. This post in a university, which on the arts side included several federated denominational universities and colleges, required great tact, broad interests, good administrative powers and the ability to bring into happy co-operation conflicting interests. This task Sir Robert successfully accomplished. As president his first duty was to administer the new constitution in a period of national expansion. The University grew in numbers, buildings, faculties and departments. The growing needs of Canada were met by increased facilities. After the interval of the War of 1914–18, a new and rapid development followed. The president was quick to recognize and to anticipate public demands for varied types of training at the university level. When he retired in 1932, the University com-

prised the Faculties of Arts, Medicine, Engineering, Forestry, Household Science, Education, Music, Dentistry, and a promising School of Graduate Studies. In fact, it had passed from the 'college' to the 'university' stage.

While always a champion of humanistic studies, Sir Robert had keen sympathy with the scientific side of university work. Indeed he had a singularly well-balanced and catholic mind. A very great advance was made in medicine, until the Faculty of Medicine became one of the chief medical schools of America. The new Toronto General Hospital, with more than 1,200 beds, became the teaching hospital of the University, and clinical services were secured also in the Hospital for Sick Children, St. Michael's and the Western Hospitals. The gift of the Connaught Laboratories by Sir Albert Gooderham provided for the manufacture of biological products; and all profits therefrom were devoted to medical research, particularly in the field of preventive medicine. The discovery of insulin in 1922, by Sir Frederick Banting, gave an enormous impetus to scientific investigation in general. Banting became the first incumbent of the Banting and Best chair of medical research, and, on his tragic death in an air crash, his chief collaborator in the insulin investigations, Dr. Charles H. Best, succeeded him. All the royalties from the sale of insulin went into medical research. The income of the Banting Foundation (about 750,000 dollars), raised to commemorate Banting's work, was devoted to the same purpose. The Rockefeller Foundation established and endowed a School of Hygiene, which has become a centre of teaching and research in preventive medicine throughout the whole Dominion. The great physics laboratory under the leadership of the late Sir John McLennan was a hive of investigation in low-temperature experiments, in the liquefying of helium, in spectroscopy. These are but examples of the general scientific life of the University. Indeed, the spirit of research permeated every part of the University, more extensively in the domain of the physical sciences but appreciably also in the humanities and the social sciences. Of all these developments Sir Robert might truthfully have said, *quorum magna pars fui*.

Although the chief support of the University of Toronto is the annual Government grant, Sir Robert Falconer found that private benefactions were not restrained. The chief of these was the princely gift of Hart House by the Massey Foundation (the inspiring genius of which was the Right Honourable Vincent Massey, now Canadian High Commissioner in England). This is a superb stone building, in collegiate Gothic style, which serves as a social centre for men from the colleges, faculties and departments of this rather variegated institution. Another gift from the same family was the building to house the Faculty of Household Science, the donor of which was Mrs. Massey Treble, aunt of Mr. Vincent Massey.

After Sir Robert Falconer's retirement from the presidency, by careful watching over his health, he was able to do much in fields which were always of special interest to him. He was president of the Royal Society of Canada, of the Royal Canadian Institute (for popularizing scientific discoveries), of the League of Nations Society, and of the Red Cross. His interest in international affairs was perpetuated by the establishment of a lectureship which bears his name; and under which the first lecturers have been Lord Baldwin and Lord Hailey.

Always dignified, sometimes austere yet kindly withal, of judicial temperament, and of deep religious convictions, Sir Robert Falconer spent a long life of high endeavour and great accomplishment. He served well the University he loved, the Dominion of Canada and the whole of the British Empire, in the beneficent mission of which he firmly believed.

H. J. CODY.

NEWS and VIEWS

University Chair in Forestry at Bangor

THE creation of a chair of forestry at the University College of North Wales at Bangor has been recently announced, and Mr. Thomas Thomson, lecturer and head of the Forestry Department there, has been appointed as the first occupant. A lecturer in forestry was appointed in the Department of Agriculture at Bangor so long ago as 1904, Mr. Fraser Story being the first incumbent. A few years later a separate Forestry Department was created, giving full degree courses. In 1912 Mr. Thomson was appointed to the Department as assistant lecturer to Fraser Story. Two years later the Department was temporarily closed down, and the two members of the staff transferred to the Timber Supplies Department. In 1919 Fraser Story resigned, being afterwards appointed to the Forestry Commission. Thomson then held sole charge of the Department until, in 1932–33, an assistant lecturer in forestry was appointed. The head of the Department had always been a member of the Senate and Faculty. In addition to his work in the Department, Prof. Thomson has done a good deal of advisory work in North Wales, and he is the author of a translation of Busgen's "Structure and Life of Forest Trees", and, in conjunction with Mr. Jerram, lecturer in the Department, of a small book entitled, "An Outline of Forestry".

Future of Pharmacy

AN address on "The Natural History and Chemistry of Drugs" was given to the Pharmaceutical Society of Great Britain by Sir Henry Dale, president of the Royal Society, on January 13, on the occasion of the award to him of the Hanbury Memorial Medal. In the course of his address, Sir Henry considered the changes in the conceptions of drugs which current advances in the medical sciences and the changing objective of therapeutics must entail, and raised the question of the future function of pharmacy under the conditions which can be foreseen. In 1932, the "British Pharmacopœia" included representative examples of the vitamins, the hormones and the immunological products, as well as some of the earlier synthetic agents of specific chemicotherapy. This represented not merely the introduction of new remedies more effective for the old purposes, but a change in the accepted aim of medicinal treatment from the relief of symptoms to the removal or prevention of the cause of disease. This will lead in due course to changes in the pharmacist's interests. Eventually the preparation of the remedies required by progressive therapeutics will fall into the hands of scientific large-scale manufacture; and the individual pharmacist will presumably become little more than an intelligent retail distributor of ready-made and centrally standardized products.

Important changes in the organization of medical practice will be necessary if the great advances which research is producing in methods of diagnosis and treatment are to be made properly available for the ordinary citizen in his home. Unless the medical practitioner is to become a mere sorting machine to secure the transfer to hospital of every case requiring serious scientific attention, he will require the services of an organization such as the common laboratory facilities which any modern hospital affords. This would require a very large number of new laboratory centres with well-trained men, and the profession of pharmacy should be interested. Some of the procedures commonly regarded as biochemical and now used in the control of some modern medication are nothing but applications to a biological vehicle, such as blood or urine, of pharmaceutical methods of assay, such as students of pharmacy still learn. Sir Henry Dale therefore suggested that "the nearest equivalent to the expert co-operation which was afforded by the work of Daniel Hanbury and the pharmacists of that old tradition to the medicinal treatment of their own days may be found under modern conditions in the aid which diagnosis and treatment still increasingly need from the laboratory".

British Coal Utilization Research Association

THE annual meeting of the British Coal Utilisation Research Association was held in London on December 15, 1943. In his presidential address, Sir Evan Williams, Bart., gave an account of the present attainments and plans of the Association, now the largest co-operative industrial research enterprise in Great Britain. The original grant by the coal owners has been doubled. It is planned to extend the research work to include the production of liquid fuels and chemical products, and for this the colliery owners are contributing in the next two or three years a fund up to £500,000. It is hoped to improve on the Fischer-Tropsch process. Efforts to increase the efficiency of coal utilization are already an important branch of the Association's work and, while bringing aid to the consumer, are anticipated to lead to a greater demand for coal. Prominent in this direction is the attention paid to the design of the open fire, for which great improvement in heat efficiency and convenience is claimed. It is a matter of experience that the greatest obstacle to technical progress is often the transference of new laboratory discoveries to commercial success. Recognizing this, the Association is planning to undertake the trial manufacture of new appliances and the pilot plant operation of new processes. For this purpose, a large site for a research station has been acquired at Leatherhead. From this, it will be seen that a scheme is envisaged on a scale worthy of so great a national problem.

It may be questioned, however, whether the ambition to increase the demand for coal is a proper ideal. In this connexion the statement that the Association aims at increasing the consumption of coal—the most precious but waning asset of Great Britain—reads curiously. War-time experience raises a question as to whether we should not be developing alternative sources of power while conserving coal for use as fuel and sources of chemical products. Moreover, it should not be forgotten that research has been and is being prosecuted by the fuel industries, and that its progress will be determined, not merely by the expenditure of money, but by the supply of effective staff.

Imperial College and 'M.I.T.'

PROF. R. V. SOUTHWELL, rector of the Imperial College of Science and Technology, London, has announced in a letter in *The Times* that the College has come to an arrangement with the Massachusetts Institute of Technology whereby the two institutions will maintain, after the War, a regular interchange of staff and postgraduate students. The Massachusetts Institute of Technology, or more briefly, 'M.I.T.', has a history of eighty years of activity which has made it known throughout the world as a centre for postgraduate instruction and research in science and technology. Indeed, it was planned specifically for this purpose, its charter stating among its purposes "the advancement, development and practical applications of science in connection with arts, agriculture, manufactures and commerce". The Imperial College in London has a very different history. It arose, as is often the way in Great Britain, by the fusion of three existing colleges, the Royal College of Science, the Royal School of Mines, and the City and Guilds College, which from being physically neighbours became associated by Royal Charter in 1907. The College provides advanced specialized instruction and equipment in various branches of science, especially in its application to industry, and is administered by a board including representatives of the Crown, the Indian Empire, the self-governing Dominions, the Board of Education, the London County Council, the Royal Society and other bodies. During the War, there has been gradually increasing interchange of information on scientific and technical developments between Great Britain and the United States, and the association of these two colleges in the intimate relationship involved in exchange of staff and students is a guarantee that Anglo-American collaboration in the fields of science and technology is to continue.

Work of Benjamin Huntsman

AT a meeting of the Newcomen Society held on January 12 at the Iron and Steel Institute, Mr. E. W. Hulme read a paper "On the Pedigree and Career of Benjamin Huntsman, Inventor in Europe of Crucible Steel". Various fictitious accounts have been given of Huntsman and his invention, and it has been said that he was the son of indigent parents. As a matter of fact he came of the Quaker family of Huntsman of Epworth, Lincolnshire, well known for their good social standing. Benjamin began his career as a watch-maker's apprentice, and he remained at this craft all his life. He set up for himself at Doncaster, about 1740–44 removed to Handsworth, Sheffield, and in 1770 to Attercliffe, where the firm he founded still is active. He died at Attercliffe in 1776. It was to remedy the defective working of watch-springs that he was led to invent a new kind of steel, and there is ample proof of his great metallurgical and mechanical skill. Cast steel made in a crucible heated in a charcoal fire supplied with a forced draught is an invention of unknown antiquity. It was known as "Wootz" steel, and was exported from southern India to Damascus, where it was called 'Damascus' steel. It was this steel Huntsman set himself to imitate, but the crux of the invention was how to make crucibles that would stand high temperatures. Of Huntsman's character little is known with certainty. At one time, it was suggested that he should be put up for election to the Royal Society, but he declined the honour.

Fungi for Food

THE larger fungi contain appreciable amounts of protein, carbohydrates and vitamins suitable for human nutrition, but their unique flavours, compounded from a plethora of little-known substances, make an even greater contribution to gastronomic variety. Dr. J. Ramsbottom is trying to stimulate interest in a wider use of our native fungi, and in a recent short paper (*J. Roy. Hort, Soc.*, 68, Pt. 10; Oct. 1943) describes fourteen species which might supplement the mushroom in our diet. The chanterelle (*Cantharellus cibarius*), blewits (*Tricholoma personatum* and the related *T. nudum*) and the morel (*Morchella esculenta*) may already be known to some connoisseurs, but the others are no less tasty. The great need appears to be for inspiration in methods of cooking. Dr. Ramsbottom has made a start in this direction, but much yet remains to be accomplished. The common *Hygrophorus pratensis*, for example, though palatable in the raw state, can be converted into a tough leathery mass by incorrect culinary preparation. All the species mentioned in Dr. Ramsbottom's paper, however, can be trusted to yield their flavour, and stimulate the palate, even with ordinary methods of cooking.

Poisonous Gases in the Exhaust of Diesel Engines

DR. ENRIQUE CASTELLANO has an article on this subject in *Publicaciones de la Facultad de Ciencias Fisicomatematicas, Universidad Nacional de la Plata* (June 1943), in which he gives a full account of his experiments to discover if pernicious effects are produced in the driver's cabin by the fumes from the exhaust. A description is given of the methods adopted for determining the amount of each of the gases ejected, and the results are summarized at the end of the paper. Comparing the figures with those for the concentration dangerous to human life for each gas, it is interesting to notice that there is a large margin in the concentration of carbon monoxide —a gas which is generally believed to be extremely dangerous in the fumes from the exhaust.

	Concentration in parts per thousand in Diesel exhaust	Maximum safe concentration
Carbon dioxide	0·77	5·5
Carbon monoxide	0·0046	0·05
Hydrogen sulphide	0·000058	0·02
Sulphur dioxide, etc.	0·00015	0·01
Oxides of nitrogen	0·0020	0·01
Aldehydes	0·000046 gm./m.^{3}	0·02 gm./m.^{3}
Carbon	0·0023	
Oils, hydrocarbons not burnt or only partly burnt	0·00046	

From these figures it appears that the concentration of gases in the cabin is far below that which is usually considered detrimental to life. In the case of the hydrocarbons and carbon, it is impossible to draw any definite conclusions, because no figures are available regarding the concentrations which are considered dangerous to human life.

Portuguese Navigators

REFERRING to the article in NATURE of November 27 on "Anglo-Portuguese Scientific Relations", Mr. Arthur J. Hughes, of Messrs. Henry Hughes and Son, Ltd., nautical and aeronautical instrument manufacturers, remarks that "the work of Prince Henry the Navigator is still being gloriously continued in Portugal. Perhaps two of the greatest navigators of the air were the late Comdr. Cabral and Admiral Coutinho, of the Portuguese Navy, who crossed the Atlantic in 1922, on the way making a brilliant landing at the Azores by close and accurate navigation. There is in Brazil to-day a great descendant of the Portuguese, Capt. Radler Acquino, who is an acknowledged expert on all methods of modern navigation. He has just published a new book of tables in Portuguese, which would delight the heart of Henry the Navigator by their simplicity. There are also tables in navigation by distinguished Portuguese navigators, Newton and Pinto, in 1930 and 1933, and there is a very close scientific connexion in nautical science and hydrography between the Portuguese and British Navies."

Newton's Verses

NEWTON's habit of transcribing passages from the writings of others has misled some writers into regarding him as something of an alchemist. Prof. E. N. da C. Andrade now concludes (*Proc. Phys. Soc.*, **55**, 426; 1943) that the same habit has misled those authors who have regarded Newton as something of a poet. When he was a boy, Newton apparently drew a picture of Charles I and wrote some verses underneath. Mrs. Vincent of Grantham repeated them by memory to Stukeley, who adds, "She fancyed, and aver'd it that he composed them himself. I rather suppose he copyed the print prefixed to the *Eikon basilice*". Prof. Andrade reproduces the verses from the "Eikon basilice". Comparison of the two versions suggests that Newton omitted the last six lines in transcribing the verses, and that Mrs. Vincent may have recollected imperfectly what he wrote. A recent biographer wrote: "These are very good verses in the fashion of the day to be written by a boy of his age". Prof. Andrade concludes: "The Eikon basilice verses, though poor and conventional, show some slight feeling for poetry. I do not think that Newton can ever have written anything even as good as this."

Comet Peltier-Kellaway

COMET PELTIER-KELLAWAY was discovered by Peltier on December 17 and independently by G. F. Kellaway, West Coker, Somerset, on December 19. Its magnitude at the time of discovery was about 6. It made its closest approach to the sun on January 19 and is becoming fainter.

Announcements

PROF. NIELS BOHR, professor of theoretical physics, University of Copenhagen, has been elected a member of the Athenæum under Rule II of the club, which permits the "annual election by the committee of a certain number of persons of distinguished eminence in science, literature, or the arts, or for their public services".

DR. R. E. MORTIMER WHEELER, director of the Society of Antiquaries and keeper of the London Museum, has been appointed director-general of archæology in India.

IT is announced that the ship-building industry in Great Britain, after consultation with the Department of Scientific and Industrial Research and the Admiralty, has decided to establish a British Shipbuilding Research Association, to develop all branches of research associated with ship-building, marine engineering and ship repairing.

Mutation and the Rhesus Reaction

IN his interesting letter[1] on genetics of the *Rh* antigen in man, Prof. L. T. Hogben advances two hypotheses. The first is that the frequency of the *rh* gene, determining the absence of the antigen, is approximately constant from one generation to another in human populations. The second is that this constancy is due to the formation of new *rh* genes by mutation, at a rate which replaces those eliminated by the deaths of heterozygotes from erythroblastosis fœtalis. Thus such populations as those of England and the United States are thought to be in equilibrium.

Prof. Hogben does not refer to the earlier work of Wiener[2] and Haldane[3] on this question, perhaps because the latter at least requires some revision in the light of later observations. Neither Wiener nor Haldane believed that the present frequency of the *rh* gene was stable, and they ascribed it to the formation of the Western European people by (geologically) recent crossing between a race in which the *rh* gene was very rare, as it is[4] in American Indians, and one in which it was very common. Haldane calculated that selection at its present intensity would reduce the frequency of *Rh*-negative individuals from its present mean American value of 14 to 1 per cent in about six hundred generations.

Whether or not the theory of racial crossing is accepted, there is a sound reason for rejecting Prof. Hogben's theory, namely, that the equilibrium which he postulates would be unstable. Let t be the time measured in generations, p the frequency of the *rh* gene, $1 - k$ the ratio of the mean viability of *Rh rh* children of *rh rh* mothers to that of other babies, and μ the frequency with which *Rh* (or a group of dominant allelomorphs) mutates to *rh* per generation. Then it follows from the argument given by Haldane[3] that

$$\frac{dp}{dt} = \mu(1-p) - kp^2(1-p)(\tfrac{1}{2} - p) + O(k^2).$$

Hence at equilibrium $\mu = kp^2(\frac{1}{2} - p)$. Among American whites $p = 0{\cdot}39$, so if they are in equilibrium $\mu = 0{\cdot}016731k$. If p is slightly increased, say, to $0{\cdot}40$, $\frac{dp}{dt} = +\,0{\cdot}0004386k$, so it will tend to increase further. If it is slightly diminished to $0{\cdot}38$, $\frac{dp}{dt} = -\,0{\cdot}000370k$, so it will tend to diminish further. If $\mu = 0{\cdot}016731k$ the only stable equilibria are given by $p = 1$ and $p = 0{\cdot}27$.

In general, the condition for stability is that $\frac{d}{dp}\left(\frac{dp}{dt}\right)$ should be negative in the neighbourhood of the equilibrium. It can readily be shown that this is only possible, whatever the mutation-rate, if $p < 1/3$. The existence of unstable equilibria between selection and mutation was pointed out by Haldane[5], and it is always desirable to investigate the stability of postulated equilibria of this kind.

While it would seem that Prof. Hogben's theory must be rejected, I do not wish to suggest that my own should therefore be accepted. Its acceptance must depend, among other things, on research into the frequency of different allelomorphs at the *Rh* locus in various populations, and I fully support Prof. Hogben's plea for more such research. This is particularly desirable in Asiatic populations where, if anywhere, a high frequency of *rh* might be expected.

IN NATURE of December 18, Prof. L. Hogben has discussed the question of gene equilibrium in the Rhesus blood-group factor, and draws the conclusion that a mutation-rate from Rhesus-positive to Rhesus-negative genes of quite unprecedented magnitude can be inferred from what is at present known of the genetic situation and the medical facts.

With the importance of obtaining direct and unbiased data of the vital statistics of marriages between different genotypes we are in most hearty agreement; and, indeed, have already taken preliminary steps toward a direct ascertainment of these factors. The situation in some respects, however, does not appear to us to have been correctly stated by Prof. Hogben; in particular, we would dissociate ourselves from the statement that "Levine's hypothesis postulates a form of adverse selection. . . ." It appears to us, on the contrary, that the evidence for Levine's theory of the causation of hæmolytic disease of the newborn is completely independent of any such postulate, and would be equally convincing whether there is or is not any such selective influence at work. It would also be wrong to infer a selective elimination of the rarer gene from a demonstrable elimination of heterozygotes, unless we knew, as we do not know, that fertility is not concurrently affected.

Finally, we do not think that Prof. Hogben's theory of an abnormal mutation-rate gains any confirmation from the rather extensive system of multiple allelomorphs of the Rhesus factor recently demonstrated at the Galton Laboratory Serum Unit and elsewhere. Speaking of his mutation-rate, Hogben says: "on the other hand, its value is not inordinately high if we interpret μ to signify the rate of mutation at the *Rh* locus from *any one of a series* of 5 or more dominant alleles". Of the seven allelomorphs we now postulate, not more than four are Rhesus-positive, while three are Rhesus-negative. Moreover, we do not see that the mutation theory is aided by the supposition that the hypothetical mutation is derived from any one rather than equally from all of the possible sources.

The Human Side of Anthropology

THE recent editorial in NATURE[1] made out a very strong case for the importance of the social sciences as a scientific contribution to the welfare of the community; and in the same issue, Prof. Le Gros Clark directed attention to some of the rich and interesting

fields open to the exploitation of the 'physical anthropologists'. As the editorial pointed out, the scope and power of non-experimental and statistical methods of analysis are becoming more widely appreciated—a movement of opinion which will undoubtedly have been encouraged by the experience of the application of science to war. It is probable, therefore, that most men of science will be disposed to wish the social scientific workers well in their endeavours to win a more favourable place in the sun.

One is also grateful for the strong emphasis which the British Association Committee on Scientific Research on Human Institutions, to which the editorial refers, has placed on the necessity for an empirical and where possible a quantitative approach. Perhaps one can recognize here the hand of Prof. L. Hogben, whose spirited invective against the more fanciful constructs of deductive theorists has so often amused and stimulated his readers in the past. But while in no way calling this emphasis in question, I wish to suggest that there is a danger that this attitude, desirable in itself, may lead to the neglect of one very important side of anthropological inquiry—indeed, the one branch of the subject which deals with those aspects of man in which he differs most completely from other animals. Human birth- and death-rates can be studied with the same theoretical apparatus as those of Drosophila; human nutrition is a problem very similar to that solved by the directors of the Zoo; 'social security', in the sense of support during illness and after retirement, we already provide for some of our domestic animals. The characteristically human is to be found in the general field of education and social life—two mutually dependent functions which together bring it about that man's evolutionary advance is mediated by processes quite unlike those found anywhere else in the animal kingdom. The study of the interrelations between the upbringing of children and the structure of the society into which they are being initiated is in its infancy, but it has been begun, particularly by American scientific workers. The Lynds and some of the Chicago school touched on it, and it has been considerably developed by authors such as Benedict, Mead and Bateson, on the sociological side, while the work of many psychologists impinges on it at another angle.

Investigations in this field have an essential part to play in solving the problems of reconstruction facing us. For example, we need to know how far it is true, and for what reasons, that the concept of 'social security' has a great appeal to British people, while to many Americans it seems to cloak the apathy of a nation which has lost its saving faith in the virtues of 'rugged individualism'. Again, we hear much of the need for the re-education of Germany; but have we any clear idea of the features in German social life which produce the attitude of unquestioning subordination to superiors, and callous domination over inferiors, that we wish to eradicate? A recent example of how such questions can be tackled is provided by the important book of Bateson and Mead on "Balinese Character" and Mead's later and more popular "—And Keep Your Powder Dry"[2].

It is much to be hoped that such studies will be encouraged in any general policy for the development of social sciences in Great Britain. The infant science needs protection, on one hand against the view that such subjects cannot be made amenable to scientific study, and on the other against the ideological contention that social characteristics spring so directly from the economic set-up that there is nothing to be gained by a close study of them.

Activity of Purified Carbonic Anhydrase

WE have shown previously that carbonic anhydrase is a zinc-protein compound[1,2] and this was confirmed by other workers[3,4]. That the catalytic activity of carbonic anhydrase, unlike the physiological activity of insulin, depends on the presence of zinc in its molecule is strongly supported by the following considerations. (1) An instantaneous, strong and perfectly reversible inhibition of carbonic anhydrase by very small concentrations of potassium cyanide, hydrogen sulphide and sodium azide which react in this way only with metals. (2) The presence of high concentrations of zinc in purified enzyme preparations obtained by different methods and from different materials. (3) The proportionality between the zinc content of different fractions and their catalytic activity. (4) The absence of other metals from purified enzyme preparations.

Our purest enzyme preparation, having approximately 2,220 enzyme units per mgm. dry weight[2], was a colourless protein containing 14·8 per cent nitrogen and 0·3–0·33 per cent zinc. As this preparation appeared homogeneous in the Tiselius apparatus[2], and in an ultracentrifuge[5], it may be considered as either pure or almost pure enzyme. It was therefore a matter of some surprise to us when Scott and Mendive[4] announced that they had obtained an enzyme preparation containing 9,000–10,000 enzyme units per mgm. dry weight with a zinc content of 0·2–0·23 per cent. Their preparations appeared, therefore, to be 4–4·5 times more active than our purest preparation. However, a careful examination of their methods of estimation of enzyme activity revealed that the high value obtained by them is only an apparent one. Their estimations were carried out in the presence of a small amount of peptone; this has the property not only of stabilizing the purified enzyme, which is very fragile in dilute solutions, but also of doubling the activity of freshly diluted purified enzyme. This factor alone would make their activity values appear at least double those given in our paper. On the other hand, peptone produces no activating effect on the carbonic anhydrase in laked blood corpuscles, which is probably due to the high concentration of proteins already available. Yet, the activity of laked corpuscles estimated by these workers was about twice as high as the value found by us. Thus in corpuscles of 18 l. of blood they found about 71 million enzyme units, whereas the same amount of blood according to our estimation contained only 37 million enzyme units.

As this discrepancy cannot be ascribed either to the possible use of peptone by these workers or to the differences in enzyme content of ox blood in Great Britain and in Canada, it can only be due to a difference in the values of the enzyme units used by us and by these workers. In this way, Scott and Mendive[4] have introduced a second factor which doubles the activity of their enzyme preparations.

The numerical value expressing the activity of their enzyme was therefore raised artificially at least four times. In other words, the activity of their best enzyme preparation expressed in our enzyme units and estimated by our method will be approximately the same as that of our pure preparation.

The comparatively low zinc content found by these workers may be due to the method of Sahyum and Feldkamp which they used and which, unlike the dithizone method used by us, requires larger amounts of zinc and invariably gives low zinc values. Their exceptionally high yield, of up to 50 per cent of purified enzyme compared with our maximum yield of 30 per cent, can only be explained by the effect of peptone which, as they have shown, doubles the activity of purified enzyme preparations.

As to the crystals of carbonic anhydrase obtained by Scott and Fisher[6], the thin plates described and photographed by them as crystals of ammonium-carbonic anhydrase show scarcely any crystalline structure and were often observed by us during precipitation of the purified enzyme. On the other hand, the crystals of alleged compounds of carbonic anhydrase with piperidine, *iso*amylamine and *n*-amylamine described by these workers have no relationship to the enzyme. In fact, these crystals, as shown by Scott and Fisher[6], are completely devoid of catalytic activity. They are obviously the crystals of salts of these bases mixed with denatured protein of carbonic anhydrase, which protects them from evaporation. They can even be obtained with gelatin instead of carbonic anhydrase.

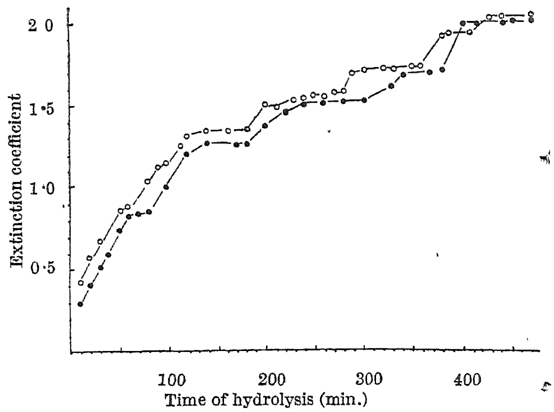
Slow Protein Hydrolysis in the Presence of 2,4-Dinitrophenylhydrazine

IN our search for reactive keto groups in the protein molecule, we found that 2,4-dinitrophenylhydrazine could be coupled with the protein framework to a surprisingly great extent (one molecule of the hydrazine to about six amino-acid residues). In a typical experiment, 100 gm. casein ("nach Hammarsten") was boiled with 1,000 c.c. 0·3 *N* hydrochloric acid and 10 gm. 2,4-dinitrophenylhydrazine. From time to time 4 c.c. samples of the mixture were removed, precipitated with 5 c.c. 10 per cent trichloroacetic acid, centrifuged, and 2 c.c. of the supernatant liquid and the whole of the precipitate dissolved in *N* sodium hydroxide, each to a total volume of 50 c.c. The extinction coefficients of these deep red solutions were measured in a Zeiss colorimeter (green filter, 0·5 cm. cuvette). When the hydrazine is not coupled, the red colour fades immediately. The intensity of the permanent colour is found to be proportional to the amount of hydrazine bound in a similar manner to that occurring in hydrazones[1].

It first occurred to us that, during hydrolysis, free amino-groups had been subjected to oxidation, and that the resulting keto or aldehyde groups had become



100 GM. CASEIN, 1,000 C.C. 0·3 *N* HCl, 10 GM. 2,4-DINITROPHENYLHYDRAZINE HEATED AT 96° WITH RAPID STIRRING. EACH POINT REPRESENTS THE MEAN OF THREE MEASUREMENTS.

coupled with the hydrazine. The ammonia produced in the hydrolysis proved, however, to be even less in the presence of the hydrazine than in its absence. This would appear to exclude the possibility of oxidative de-amination, which would necessarily involve the freeing of ketonic acids into the solution. Furthermore, it was found that most of the hydrazine was coupled to the high-molecular fraction precipitable with trichloracetic acid. Spectrometric investigations of the red colour formed here, and that arising in the dissolution of pyruvic acid 2,4-dinitrophenylhydrazone in alkali, showed that the absorption spectra were almost identical in the two cases. It would thus seem that, at least after a short period of hydrolysis, groups are present in the protein framework which, without being ketone or aldehyde structures, permit the coupling of the hydrazine in the normal manner, that is, with the formation of the group =N—N=CR—. It may be mentioned that the dipeptides of amino-acids (for example, glycyl glycine and leucyl leucine) do not give this reaction. Tyrosine and arginine give very weak reactions of the same type.

A consideration of the possible seats of the reaction has led us to the tentative conclusion that the occurrence of amidine groups in the protein framework would provide an explanation for the observed phenomenon. A mechanism for the formation of the amidine structure in the protein framework may be found in the condensation of two adjacent peptide bonds, one of the normal and one of the enolized type:

$$\begin{array}{c} \text{—C(OH)=N—} \\ \text{—NH—CO—} \end{array} \longrightarrow \begin{array}{c} \text{—C=N—} \\ | \\ \text{—N—CO—} \end{array}$$

An arrangement of such amidine groups regularly distributed through the protein molecule permits a rigid fixation of the polypeptide chains into a framework more clearly defined in the crystalline sense. During hydrolysis in the absence of hydrazine, the amidine groups may each take up one molecule of water, thus causing disintegration into polypeptide chains, which may then be subject to further hydrolysis. The hydrazine molecule may break the —C=N— bonds of the amidine structure and thus become coupled with the high-molecular framework.

Experiments with benzoyl aminoacetamidine and other amidines show that these all react with 2,4-dinitrophenylhydrazine, giving very strong colour reactions of the same type. It is, indeed, well known

that amidines react with phenylhydrazines in such a manner that the imino group is exchanged for the reactive group of the hydrazine.

It is also of interest to note that the reaction of the 2,4-dinitrophenylhydrazine under our mild hydrolytic conditions is by no means continuous. Curves showing the relation between time of hydrolysis and colour intensity of the solution in sodium hydroxide of the fraction precipitated by trichloracetic acid exhibit definite discontinuities which are, in principle, reproducible. A pair of typical curves is shown in the accompanying graph. While no explanation of the phenomenon can be given at present, it is conceivable that it is connected in some manner with a successive destruction and regeneration of groups capable of fixing the hydrazine. This in turn may be related to the discontinuous liberation of tyrosine and arginine which we have observed colorimetrically in the filtrates from the trichloracetic acid precipitations in the absence of 2,4-dinitrophenylhydrazine.

An extended account of this work will be published elsewhere.

Distribution of Nucleic Acid in the Cell

THE statements which Stedman and Stedman[1,2,3] have published in NATURE must, it seems, be considered from two points of view. First, there is their chemical analysis leading to the discovery of "chromosomin". Secondly, there are the biological consequences which they have inferred from this discovery. Clearly, the chemical analysis is the foundation of everything else; but since no particulars of this analysis have been published, we can deal only with the superstructure.

The chief of Stedman and Stedman's inferences concerns the distribution of thymo-nucleic acid in the nucleus. They infer that the bulk of the thymonucleic acid lies in the nuclear sap, not in the chromosomes. Their own tables, however, demonstrate the contrary. They have determined the proportion of thymonucleic acid in the dry weight of nuclei varying between the extremes of no nuclear sap in cod sperm to, say, 90 per cent in carcinoma cells. The small variation in proportion of thymonucleic acid is not correlated with the proportion of nuclear sap. Yet it is on the basis of these results that Stedman and Stedman proceed to dismiss the work of Mazia and Jaeger, Caspersson, Norberg and Barigozzi[4], who by four different methods have converged on the conclusion that thymonucleic acid exists in the cell only in structural relationship with the chromosomes.

This conclusion continues to be reinforced by new evidence. For example, Claude and Potter[5] have recently, by a simple technique, isolated chromosome threads from resting nuclei. By chemical analysis of the threads they conclude that 40 per cent is thymonucleic acid, which agrees closely enough with the proportion determined by Norberg, and the threads were, of course, Feulgen positive. Thus thymonucleic acid was evidently attached to the chromosome threads before their isolation. Stedman and Stedman's theory of indirect staining by Feulgen's reagent becomes meaningless in the light of this experiment. On the other hand, Choudhuri's observation[6] of the staining of chromosomes by "developed Feulgen reagent", which has been used by Stedman and Stedman in support of their theory, is, of course, merely another example of the use of a basic dye.

Stedman and Stedman's view that thymonucleic acid is the main solid constituent of the nuclear sap leads them further: "it is an attractive hypothesis", they say[1], "but one for which there is no direct experimental proof, that the spindle which is formed at metaphase is a gel of nucleic acid". Later[3] they state, without additional evidence, that "there seems little doubt that nucleic acid is concerned mainly with spindle formation".

Darlington[7] has given reasons for believing that the development of the spindle depends on a reaction between the centromeres of the chromosomes and fibre-forming molecules of a type not usually found within the nuclear membrane. The spindle can therefore develop only after the breakdown of the nuclear membrane. With regard to the nature of these fibre-forming molecules, most workers have contented themselves with the evidence that the spindle, like other cytoplasmic constituents, does not contain thymonucleic acid. On this point the work of Schmidt and others on birefringence is directly significant. Schmidt[8], Runström[9] and Nakamura[10] have shown that the spindle fibres are positively birefringent with respect to their length, whereas pure sodium thymonucleate fibres are negatively birefringent, thus giving the peculiar optical properties actually found in the chromosomes.

In the light of this evidence, we feel that the position and function of "chromosomin" in the nucleus will have to be determined in relation to the already well-established position and function of thymonucleic acid.

Influence of an Adsorbed (Inner) Layer on the Cohesion of a Solid

IN a previous communication[1] attention was directed to the influence of adsorption in causing the phenomenon of floating drops. In other words, an adsorbed layer (in particular of gases), when enclosed within a liquid, may lessen its cohesion so that no coalescence takes place, the adsorbed layer acting as a barrier. Thus a drop of molten paraffin—where adsorption may be expected—persists for a relatively long time, say, 1 min., on a paraffin surface.

These observations were extended to solid paraffin, using the following principle. Two plane surfaces

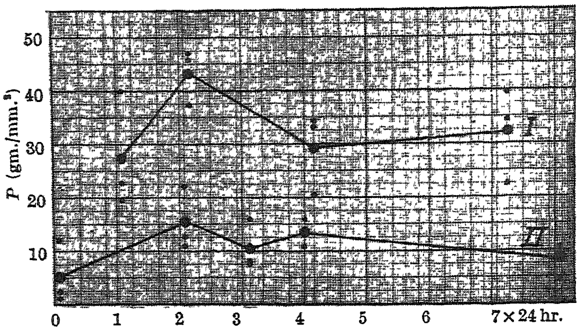

Fig. 1.

of two paraffin cylinders, if brought into contact under a definite pressure, will stick more or less firmly. This provides a measure of the resulting cohesion at the contact surface. Two cases may be considered: (1) If the surfaces have been formed by cutting at room temperature, no sensible adsorption is to be expected. (2) If the cut specimens have been exposed to tempering, a sensible adsorption in the surfaces may be expected. Accordingly, a lessened cohesion ought to occur.

Small cylinders of paraffin (melting at 68–72° C.) were cast in a shape permitting traction tests to be performed. The plane surfaces were smoothed, using a special, sharp turning tool. Two cylinders were pressed together in a small press, using constant load, and time.

The following figures were first obtained.

Treatment after plane turning	Average 'tensile strength'
No tempering	323 gm.
Tempering at 40° C., 17 hr. ..	320 ,,
Tempering at 50° C., 17 hr. ..	17 ,,

While tempering at 40° had practically no effect, tempering at 50° gave a strikingly low tensile strength, intimating that effective adsorption had occurred.

The final tests are exemplified by Fig. 1. The specimens tempered at 50° C. (II) show a considerably lower strength than the untempered ones (I), confirming the above result. Similar data were obtained with paraffin melting at 75–80° C.

Thus, *an adsorbed layer considerably lowers the cohesion appearing in solid paraffin.*

This having been established, similar tests were attempted on lead. The cut surfaces were brought together (1) as soon as possible after cutting, and (2) after a definite period t, permitting the air to form a thin foreign layer on the surfaces. This foreign layer was found strongly to diminish the cohesion. The results, however, were irregular, on account of too rapid formation of the adsorbed (oxide) layer.

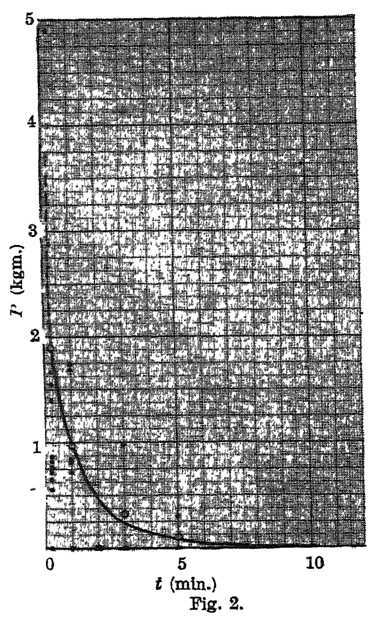

Fig. 2.

Tin was found to be more appropriate. Fig. 2 illustrates the tensile strengths P obtained after different times t of exposure after cutting. It will be seen that the average values (circles) lie fairly well on a smooth curve. This gives evidence that on increasing exposure time t a striking decrease of the sticking power occurs, so that after $t = 10$ min., no sticking whatever was obtained. At first the slope of the curve is very steep. We infer that even an extremely thin adsorbed layer strongly diminishes cohesion with solid tin.

The conclusion is thus that the action exerted by a thin (adsorbed) layer in lowering cohesion, which has been evidenced for different liquids and now for solid paraffin, likewise occurs in the case of a solid metal (lead and tin). This experimental result is important in the phenomenon of grain growth in metals.

Further details will appear in *Arkiv för Matematik, Astronomi och Fysik*, vol. 30 A, of the Royal Swedish Academy of Sciences, Stockholm.

Biology of the Malarial Parasite in the Vertebrate Host

DURING the last few years an increasing amount of interest has been centred in the so-called exoerythrocytic stage which has been demonstrated in the life-cycle of certain malarial parasites of birds. The first really clear proof that schizogony of a malarial parasite could occur in cells other than red blood corpuscles was given by Huff and Bloom[1], who demonstrated that *Plasmodium elongatum* successfully parasitized not only erythrocytes, but also monocytes and lymphocytes, and a variety of cells in the bone-marrow and the spleen. Next Raffaele[9] described some tissue forms of *Plasmodium relictum* found by him in canaries which had been infected by means of sporozoites, but it was the work of James and Tate[4] which finally attracted the attention of malariologists all over the world to the possible great importance of what they called an exoerythrocytic stage in the life-cycle of malarial parasites. They found that the schizogonic cycle of *Plasmodium gallinaceum* in chickens took place not only in the erythrocytes, but also in endothelial cells throughout the tissues of the body. The parasites in the endothelial cells developed to a much larger size than in the erythrocytes, and also, because of the absence of hæmoglobin from the host cells, they were unpigmented. They were plentiful in the endothelial cells of the brain and spleen, but easily found, too, in the liver, lungs and kidneys. They were present in much greater numbers in an infection induced by sporozoites than in an infection induced by simple inoculation of infected corpuscles[3]. A feature of these exoerythrocytic parasites was their great refractoriness to drugs such as quinine and atebrin,

and it was suggested that such forms might be present in human malaria and constitute the explanation of why relapses so frequently occur. Clearly, this suggestion made the problem of exoerythrocytic forms of the greatest possible importance.

The work of James and Tate has been confirmed many times, and in addition exoerythrocytic forms have since been described in other malarial parasites of birds; for example, in *Plasmodium circumflexum*[7] and in *Plasmodium cathemerium*[5,6]. Sometimes these forms have been found only if the infection in the bird has been induced by sporozoites, although it has been claimed[7] that they are present in *Plasmodium circumflexum* infections if these have been induced by inoculation of parasitized cells (for a full review of the position, see Porter and Huff[8]). Experiments in these laboratories indicate, however, that the exoerythrocytic forms described by different workers in different species, and in different stages of the disease in the same species, are not all analogous stages in the life-history of the malarial parasite, and that, in fact, the only feature they may have in common is that they do not occur in red blood cells. Because of the War these experiments cannot be described in detail, but it is felt that the conclusions which they have suggested should be published because they help to clarify the problem of exoerythrocytic schizogony. The conclusions are:

(*a*) When sporozoites are introduced into the blood stream they do not persist there for more than a short time (a matter of minutes in the case of sporozoites of *Plasmodium gallinaceum*), but quickly penetrate the tissues.

(*b*) Within the tissues they pass through a developmental phase. The duration of this 'primary tissue phase' constitutes the incubation period of the infection or, more strictly, the prepatent period. Recently, the name cryptozoites has been given to the parasites of the primary tissue phase[2].

(*c*) Following the end of the developmental primary tissue phase there is a release of parasites into the blood stream and, in the case of *Plasmodium gallinaceum*, into further tissue cells, giving rise to a secondary tissue phase (the original exoerythrocytic stage of James and Tate).

(*d*) The primary tissue phase is essentially developmental and only follows the introduction of sporozoites; the secondary tissue phase of *Plasmodium gallinaceum* may be formed from the primary tissue phase or it may be initiated by blood parasites. Unlike the primary tissue phase the secondary tissue phase is capable of indefinite schizogony, and may persist as long as an infection lasts.

(*e*) The primary tissue phase and the secondary tissue phase react differently to certain drugs.

In diagrammatic form these conclusions can be illustrated as follows:

$$\begin{tikzcd}
 & & \text{blood phase} \arrow[dr, shift left] & \\
\text{sporozoites} \arrow[r] & \text{primary tissue phase} \arrow[ur] \arrow[rr] & & \text{secondary tissue phase.} \arrow[ul, shift left]
\end{tikzcd}$$

It seems to us that the primary tissue phase is probably common to all malarial parasites, but so far the secondary tissue phase has been described definitely only in the case of *Plasmodium gallinaceum* and, if the term exoerythrocytic is used literally, in the case of *Plasmodium elongatum*, but probably, also, in the case of *Plasmodium circumflexum* and *Plasmodium cathemerium*. The secondary tissue phases of *Plasmodium elongatum* and *Plasmodium gallinaceum* are quite different from one another, and it might well be that this phase is a specialized feature of only a few malarial parasites, taking a different form in the different species—its great development in *Plasmodium gallinaceum* is certainly specialized. It remains an urgent problem to determine whether a secondary tissue phase exists in any of the species causing human malaria, because in it lies an answer to the problem of relapses.

The conclusions have their bearing on the problems of malarial chemotherapy. It will be clear that there might be as many as five forms of a malarial parasite which react specifically to drugs, namely, the sporozoite, the primary tissue phase, the secondary tissue phase, the schizonts of the red blood cells and the gametocytes. A true causal prophylactic drug will act either on the sporozoites or on the primary tissue phase, but a drug which suppresses the blood phase as it arises from the primary tissue phase will simulate causal prophylactic action which, we think, is what Mepacrine (atebrin) sometimes does when it is taken prophylactically; at least we have no evidence that it kills sporozoites, and we know that it does not kill the primary tissue phase in bird malaria.

Manganese Hunger in Animals

WHILE engaged in an investigation, under the auspices of the Indian Research Fund Association, on the role of manganese in the synthesis of ascorbic acid by animals, an interesting observation has been made.

Rabbits were kept on a synthetic diet of purified ingredients and suitably supplemented to make it complete in the known factors except ascorbic acid. The salt mixture given was a modified salt mixture No. 185 of McCollum and Davies. When the animals were housed together in cages provided with galvanized screen bottoms, they were found, after a time, to pluck one another's fur and eat it. They also went greedily after whatever came their way by chance such as wood, cork, etc. The controls, supplemented with manganese, did not exhibit any such unusual behaviour. Rats kept on similar manganese-free diet also showed, in contrast to controls supplemented with manganese, a hankering for wood, cork, thread, etc., whenever they could get at them. They also licked the metal of the cages. When kept on this diet for a long period, they ceased to grow normally and eventually the experimental animals started dying out. Post-mortem examination revealed hæmorrhages of the lungs, liver and the intestinal capillaries. Once, when one animal out of a group of four died, the survivors ate the viscera of the dead one.

The plucking and eating of one another's fur by the rabbits, the eating of the dead animal's viscera by the surviving rats and the hankering of the manganese-deprived animals for any titbits seem to have been due to the lack of manganese in the diet.

Chalk Brood Attacking a Wild Bee

A PIECE of partly decayed deal tunnelled by an insect received for identification in September from Acton, London, was found to contain the nest of a leaf-cutting bee, probably a Megachile sp. The wood had been split for firewood and only one cell of a series in the tunnel remained intact. The cells were formed by lining the tunnel with pieces cut from hawthorn leaves and contained a dead pupa and a food store consisting of a pellet of pollen massed together with honey. The pollen proved to be that of a composite with spiny grains 35–42 μ in diameter comparable in size and ornamentation with those of the creeping thistle, *Cirsium arvense* Scop. The purity of the pollen store suggests that this wild bee confines its attention to one species of plant at a time, a habit regarded as characteristic of the honey bee. The pupa and pollen store were invested with a white mycelium in which small black fruiting bodies were observed. On examination the fungus proved to be *Pericystis apis* Maassen, the pathogen responsible for the chalk brood disease of the honey bee. We are not aware of earlier records of this fungus attacking wild bees, though this may not be due to a scarcity of the fungus but to the infrequency with which such material comes under the notice of a mycologist.

The So-called Plücker's Plane

ONE is accustomed to see 'Plücker's plane' explained as an effect of a magnetic field on particles which, supposedly paramagnetic, arrange themselves somewhat as iron filings would.

I have observed, however, that the effect is wholly explained by the ordinary magnetic deflexion of the slow-speed cathode rays, which, issuing normally from the cathode and projecting secondary ions beyond their own range, cause, with a cylindrical cathode, the familiar cylindrical negative glow. In fields of 200–300 gausses or more, a substantially regular 'plane' appears, because all particles not originally travelling along the lines of force (that is, in 'Plücker's plane') are dissipated by the strong magnetic deflexion; but in weaker fields, of 100 gausses or less, the process of magnetic deflexion from the other parts of the cylindrical glow is very evident—in opposite directions on the two sides of the 'plane'—and this explanation is further shown to be correct by asymmetrical displacement if the poles are inclined. The more intense spots of light near the poles, if these are conical, are due to spiralling concentration along the lines of force. Again, the 'plane' is unaffected by a change from knife-edge to extensive plane poles, although in the latter case the field is uniform throughout the tube. If two poles near one another are brought to one side of the tube, so as to give the greatest possible field gradient, there results a dark space opposite the gap, due to deflexion away from there, whereas 'magnetic' particles would fill this space more densely than in the absence of the field.

If the 'ions' have any paramagnetism, it is not apparent under these various conditions. The 'hoariness' of the fallacious view of this nearly century-old experiment is remarkable, seeing that it requires the supposition of some novel kind of intensely magnetic ion formed near the cathode.

Metallic Searchlight Mirrors

IN my Parsons Memorial Lecture delivered before the Physical Society on October 15, 1943, and published in NATURE of December 10, I said that "Metal searchlight mirrors, though occasionally revived, are now almost obsolete, at any rate in Great Britain, owing to the inferiority of reflecting power and the difficulty of maintaining it good under service conditions"; this statement was in accordance with what I had been able to find in print, and with what I had been able to learn personally concerning military searchlights. A certain type of metallic mirror had, in fact, been recently discarded from the service.

I now learn from Messrs Clarke, Chapman and Co., Ltd., of Gateshead-on-Tyne, that after spending a large sum on development, they have been able to overcome the difficulties, and are making metallic mirrors which are able to stand service conditions.

I knew nothing of this at the time of writing and regret not having made fuller inquiries before undertaking to say anything about the subject.

It is hoped that this letter may correct any harm that has been done.

RAYLEIGH.

Terling Place,
Chelmsford.

J. B. Hannay and the Artificial Production of Diamonds

WITH regard to Dr. Travers' letter in NATURE of December 18, p. 726, Mr. Hannay and my father were partners in some of his industrial developments. Some time after the diamond experiments were made, I remember attempts to piece together certain fragments under the microscope. I understood that Mr. Hannay was concerned lest some practical joker had interfered with the experiments as had been suggested. He, himself, was not the type of man to fake a result. He was certainly interested to check that no one else had.

RESEARCH ITEMS

Tent Caterpillar in India

K. A. Rahman and A. N. Kalra have described the life-history of the tent caterpillar (*Malacosoma indica* Wlk.) in the Simla Hills (*Proc. Indian Acad. Sci.*, 18, Sect. B, No. 2; 1943). The egg masses, resembling those of the notorious tent caterpillar of America, were found deposited on branches and twigs of a number of apple, and a few pear, trees, during the course of an entomological survey of the orchards in the Kotgarh ilaqa (Simla Hills) in July–August 1940. The eggs hatched out in the laboratory at Kotgarh were kept under observation, and in due course the adults were identified as *Malacosoma indica*. The pest has been recorded from apple, pear, apricot, walnut, *shaigal* (Pyrus sp.) and *ban* (*Quercus incona*), the apple suffering most severely and occasionally the pear. The pest hibernates in the egg stage, the females laying eggs as broad bands around branches of the plant, each band covered by a protective layer of dark brown gluey substance. When buds appear (about the middle of March) the eggs hatch out. The egg-stage lasts for about nine or ten months. The larvæ live gregariously, and soon after hatching spin a silken nest or tent in a sheltered place on the plant. As the larvæ grow the tent increases, finally reaching a length of 1–1½ ft. There may be eighteen to twenty-five tents on each plant. The larvæ live in the tent by day and eat the leaves of the plant at night. When fully fed, the larvæ spin silken cocoons in protected places and pupate. The duration of life is from thirty-nine to sixty-eight days. There is only one generation in a year, the moths emerging in May and June, the duration of the total life-cycle being about a year. The entire plant may be stripped bare of leaves, only the ribs and harder veins remaining, and such plants bear no fruit. In the absence of leaves the young caterpillars may eat the tender bark.

Researches on Indian Myxosporidia

M. CHAKRAVARTY has described twelve species of Myxosporidia parasitizing fishes ("Studies on Myxosporidia from the Common Food Fishes of Bengal", *Proc. Indian Acad. Sci.*, 18, Sect. B, No. 2; 1943). Eight of these are new species and the remainder are little known in India. Most of the fishes studied were collected from local tanks or purchased from Calcutta markets. Some were kept in large aquaria in the laboratory. Most of these parasites were in the gall bladder, but one of them, *Myxobolus clarii* n.sp., was also found in the liver, testes, ovary and fat bodies, and two, *Myxobolus catlæ* n.sp. and *Thelohanellus rohitæ* (Southwell and Prasad), in the gills. Infection experiments of the fingerlings of those fishes acting as hosts for *Myxobolus catlæ* proved fatal under laboratory conditions. The parasites, particularly the spores, were mainly observed in the fresh condition, different reagents being used for special purposes.

Free Border of Intestinal Cells

A LITTLE more than a hundred years ago Henle described a free border, *freie oberfläche*, in the intestinal cells of vertebrates. Since then, owing to its obvious importance from the point of view of absorption, it has been studied by a number of authors and received a variety of names according to the interpretation of its striated appearance as seen in section. Two major conflicting interpretations have been set forth; in one it is considered to be composed of cilia or rods, and in the other the striation is supposed to result from the presence of pores or canals. The latest investigation of this interesting topic by means of most careful and modern technique is that by John R. Baker (*Quart. J. Micro. Sci.*, 84; 1942). He is a supporter of the pore theory and considers that the free border in Tetrapoda consists of a layer next to the lumen of the intestine perforated by a number of pores, a thicker layer traversed by canals at right angles to the surface and communicating with the pores, and lastly a granular layer which lies next to the cytoplasm of the cell. The suggestion is put forward that unhydrolysed fats pass through the canals in extremely fine droplets.

Nemertean Worm of the Genus Gorgonorhynchus

IN 1930 W. J. Dakin discovered a new type of Nemertean worm in Australia which he placed in a new genus, Gorgonorhynchus, and reported it in NATURE (128, 796; 1931). While typically heteronemertean in all other respects, it differs from all other members of the group in having a much branched proboscis instead of an unbranched one. In 1931 Dakin received material from India which showed it to be present there also. The following year Dr. F. J. G. Wheeler, without any knowledge of these discoveries, collected it in the Bermudas, and he has now published a discussion on its possible bearing on evolutionary theory (*Amer. Nat.*, 1943). The author points out that it was found in these three widely separated regions at about the same time but was previously unnoticed in any of them. Moreover it is common, found intertidally at all times of the year and is large enough not to escape detection by shore collectors. Marine zoologists had collected in the same areas previously, and in the Bermudas particularly two experts on the Nemerteans, Verrill and Coe, had collected intensively on the same beaches where it is now common. Dispersal may account for its appearance in India and Australia but can scarcely be held to explain its turning up in Bermuda within such a short time. The author suggests, as a possibility, an almost simultaneous gene mutation in closely related members of a group of Heteronemerteans.

Studies of Hydracarina

IN two recent publications, O. Lundblad has made noteworthy contributions to our knowledge of the Hydracarina. One (*Arkiv. Zool.*, 24; 1942) treats of those from Madeira, and the other (*Kungl. Svenska Vetensk.*, 20; 1943) those belonging to the genus Koenikea *sens. lat.* from Brazil. Both are fully illustrated by text figures and by plates containing numerous reproductions of photographs, many of them of types or allotypes. From Madeira 25 species are described and of these 24 are new or, if previously reported in brief by the author, are here more fully described with their nymphs. In spite of this large number of endemic forms only one genus, Maderomegapus, is so far peculiar to the island, and indeed all the other genera have been recorded from Great Britain. The genus Koenikea is one of the richest in species of all the South American genera and is represented by 49 species and 13 varieties, whereas in North America only 6 species of it are known. 71 species and varieties are dealt with in the text, and appended to it are a

key to the 11 subgenera of Koenikea found in South America and another key to the American species of the genus.

Studies of Bryozoa

IN two recent publications from Brazil (*Bol. Faculd. Filos. Cien. e Letr. Zoologia*, No. 5, 1941 and No. 6, 1942) E. Marcus has described a number of points in the structure and development of a whole range of Bryozoa including Entoprocta, Ectoprocta and Phylactolæmata. The papers are illustrated with 22 plates and both plates and text are unusually well produced; fortunately also for many readers each paper is provided with an adequate summary in English. While the work is mainly concerned with structural and developmental features, it does nevertheless bring out a number of points that are useful from the systematic aspect. In the earlier paper the author describes in detail the life-history of *Nosema bryozoides*, a microsporidian parasite of the Bryozoa, here occurring as *Stolea evelinæ*.

Noise Measurements in Vacuum Tubes

IN long-distance transmission systems, there must always be an adequate margin between signal and noise. Noise introduced at the point where the signal level is at its lowest—that is, at the input to each amplifier—will limit the permissible line attenuation and hence the length of line between repeater stations. Close control of tube noise is therefore of importance in keeping down the cost of the system without sacrificing telephone quality. Noise output of an amplifier the input circuit of which is a pure resistance is the sum of the effects of thermal noise in the input resistance and of tube noise. If the amplifier had a perfectly quiet tube in its first stage, the noise measured by a meter in the output circuit would be due to the thermal noise. Replacing the quiet tube by an average tube would increase the power output of the amplifier by an amount due to tube noise. Several measuring sets for determining tube noise have been devised on this principle. A new one, described in an article by J. J. DeBuske (*Bell Lab. Rec.*, 21, No. 12; August 1943), was set up to meet the need for a fast and simple method of measuring, under actual operating conditions, the noise contributed by a tube in the first stage of the line amplifier in *K*1 carrier systems. The 135-ohm input termination is connected to the input circuit of amplifier No. 1, which is the *K*1 carrier line type. This input circuit consists essentially of a transformer with impedance ratio of 135 : 30,000 and a 30,000 ohm termination on the high side which is connected to the grid of the tube under test. An attenuator, a filter, a second amplifier and a calibrated thermocouple meter, which serves as a power-measuring device, complete the equipment.

Dimethyl Ether Compound with Boron Trifluoride

CONSIDERABLE interest is attached to the compound formed from dimethyl ether and boron trifluoride in which presumably a co-ordinaté (or donor-acceptor) link between the boron and oxygen is present $(CH_3)_2O \rightarrow BCl_3$. The structure of the molecule has now been investigated by the electron diffraction method (S. H. Bauer, G. R. Finlay and A. W. Laubengayer, *J. Amer. Chem. Soc.*, 65, 889; 1943). The boron valency angles are tetrahedral, the distances are B—F $1 \cdot 41 \pm 0 \cdot 02$ A., B—O $1 \cdot 52 \pm 0 \cdot 06$ A. The ether part remains essentially unaffected: at most, the C—O separation is increased from 1·42 to 1·44 A. It is probable, but not certain, that the oxygen valency angles are tetrahedral. The conclusion reached from energy considerations is that the bond formed between boron and oxygen is due to an electron pair rather than to dipole-dipole interaction.

Partition of Energy among the Stars of the Galaxy

THE results of an important statistical study of stars of different spectral types are summarized by Vyssotsky and Williams in the current *Astrophysical Journal* (98, 185; 1943), and are discussed by them in a paper which follows (p. 187). The basis of the work is a spectral classification of 7,600 stars in 441 sample regions distributed fairly uniformly over two thirds of the sky. The plates were taken on the 10-in. prismatic camera of the Leander McCormick Observatory, and the counts are complete down to photovisual magnitude 11·5. The data are discussed from the point of view of galactic concentration, and it is plainly shown that for stars at the same distance the dwarfs cluster much more closely to the galactic plane than do the giants. A surprisingly close representation of the curves connecting observed star density with galactic latitude can be obtained by assuming equipartition of energy among the stars of the main sequence. The much smaller apparent concentrations of stars of the giant branch are consistent with larger kinetic energies; *K*-type giants, for example, have velocities perpendicular to the galactic plane which are twice as big as those of the *A*-type stars. This evidence strengthens that already obtained from a recent McCormick investigation in which the mean kinetic energy of dwarf *M* stars, selected without regard to their proper motions, was found to be equal to that of the *A* stars. Evidently the Galaxy in our vicinity must be regarded as an imperfect mixture of two kinetic systems, in one at least of which (the main-sequence stars, or dwarfs) equipartition of energy prevails.

Origin of the Zodiacal Light

A NEW theory of the zodiacal light is given in a paper by V. G. Fessenkoff (*Astro. J. Soviet Union*, 19, No. 4; 1942) summarized in the current issue of the *Astrophysical Journal* (98, 129; 1943). That the light is sunlight scattered by small dust particles is now common ground; the problem consists in accounting for the existence in the solar neighbourhood of an oblate cloud of cosmic dust of density decreasing somewhat more rapidly than the inverse distance from the sun. The new hypothesis is that this matter arises from collisions between sporadic meteors and the asteroids. It is known that planets and satellites devoid of an atmosphere are subjected to a meteoritic bombardment which is probably responsible for their observed surface layers of pulverized rocks. The small asteroids suffer the same bombardment, but their gravitational attraction is not enough to retain the resulting dust particles; and since their total surface is enormously greater than that of a major planet, the process of dust production must be especially efficient in the asteroid zone. Fessenkoff finds that a dust cloud produced in this way will form an oblate spheroid, with the sun at its centre, surrounded by a dense ring of particles in the asteroid zone. The former is responsible for the conical zodiacal light: the latter for the uniform zodiacal band visible along the entire ecliptic throughout the night.

NITROGEN LOSS FROM SOILS AND OXIDE SURFACES

By PROF. N. R. DHAR and DR. N. N. PANT
Indian Institute of Soil Science, Allahabad

IT has been reported[1] that when a virgin soil is brought under cultivation, the percentage of total nitrogen usually falls off with time up to a limiting value. A loss of nitrogen from soils on the addition of nitrogenous compounds, especially when the conditions are favourable for oxidation, has also been observed by different investigators; but this phenomenon has been explained satisfactorily by Dhar and collaborators[2], who have postulated that this type of nitrogen loss in soils is chiefly due to the formation and decomposition of the unstable ammonium nitrite produced in the processes of ammonification and nitrification. There is also the possibility of the reaction of nitrous acid on amines, amides and amino-acids which may sometimes be present in the soil or formed in the decomposition of soil organic substances. It has also been reported that soil loses nitrogen in the form of nitrogen gas much less when manured with sodium or potassium nitrate than when treated with ammonium sulphate, urea or other organic nitrogenous manures.

It has been shown in a number of papers that this phenomenon of denitrification is accelerated by light and by the presence of acids, and markedly retarded by carbonaceous substances like sugar, molasses, cellulose, etc. The loss of nitrogen is enhanced by increase of temperature, and at the same temperature this loss is much greater in sunlight than in the dark. From our experiments on the processes of ammonification and nitrification of different nitrogenous compounds in presence of sterile and unsterile soils and with photo-active surfaces like titanium oxide, zinc oxide and iron oxide (Fe_2O_3), it has been concluded that the amounts ammonified and nitrified and the loss of total nitrogen are much greater in light than in the dark in both sterile and unsterile conditions, and the phenomena of ammonification and nitrification can take place in the complete absence of micro-organisms.

In order to establish that the phenomenon of denitrification can be a non-bacterial process, careful experiments under completely sterile condition have recently been carried out. 2 gm. urea and 2 gm. gelatine are first autoclaved in the dry condition in a number of boiling tubes for 10 minutes at 15 lb. pressure. These substances were added under aseptic condition separately to 600 c.c. Pyrex glass flasks, some containing 100 gm. sterilized soil with 100 c.c. autoclaved distilled water, and others containing only sterilized oxides (1 gm. titanium oxide and 0·1 gm. zinc oxide) with 50 c.c. autoclaved distilled water. To one set of these flasks, previously sterilized, glucose was added, and finally all the flasks are sterilized by steaming for more than twenty minutes. One set of flasks was covered with black cloth to cut off light and the other set exposed to sunlight for 8 hours every day. In order to eliminate the temperature effect, the dark set was also placed in sunlight. The exposure continued for 650 hours. At the end of the exposure, all the sets were tested and found free from any bacterial contamination. The contents of the flasks were analysed for total carbon and nitrogen at the end of the exposure, after adding a few drops of dilute sulphuric acid to prevent loss of ammonia during analysis. The following results were obtained:

TABLE 1. EXPERIMENTAL FLASKS UNCOVERED IN SUNLIGHT.
Total nitrogen introduced in soil sets = 289·3 mgm. in oxide sets = 249 6 mgm. nitrogen.

	Total carbon introduced (gm.)	Total carbon unoxidized (gm.)	Total carbon oxidized (gm.)	Total nitrogen (mgm.)	Total loss (mgm.)
	per cent	per cent	per cent	per cent	per cent

TABLE 4. EXPERIMENTAL FLASK COVERED.

	Total nitrogen introduced (gm.)	Total nitrogen unoxidized (gm.)	Total nitrogen oxidized (gm.)	Total nitrogen (mgm.)	Total nitrogen loss (mgm.)
	per cent	per cent	per cent	per cent	per cent
(1) Soil + urea + 0 gm. glucose	0·8842	0·7977	0·0865	953·20	21·40
(2) Soil + urea + 1 gm. glucose	1·2842	1·1094	0·1748	966·30	8·30
(3) Soil + urea + 3 gm. glucose	2·0542	1·8417	0·2425	969·00	5·60
(4) Soil + urea + 5 gm. glucose	2·8842	2·6030	0·2812	971·40	3·20
(5) Oxides + urea + 0 gm. glucose	0·40	0·3498	0·0502	922·60	10·8
(4) Oxides + urea +1 gm. glucose	0·80	0·6982	0·1018	927·70	5·7

From the foregoing results it is clear that nitrogen is lost both in soil and with oxide surfaces on the decomposition of urea and gelatine, even in the complete absence of micro-organisms. The loss of nitrogen is greater in light than in the dark. No doubt the denitrification is much less with the oxide surfaces than with the soil, but the surface offered by the oxide is much less than that presented by the soil. Moreover, the addition of glucose markedly reduces the amount of denitrification of urea and gelatine in the light as well as in the dark. These results confirm that non-biological denitrification is possible and that light accelerates the process in a marked manner.

AGRICULTURAL EDUCATION ASSOCIATION CONFERENCE

THE half-yearly meeting of the Agricultural Education Association, which was held during January 4–5 at the London School of Hygiene and Tropical Medicine, concerned itself partly with problems of a direct educational interest, and partly with matters of a more technical nature.

A considerable amount of time was devoted to a consideration of the agricultural education of the youth of fifteen and older, a very topical subject in view of the impending changes in the educational scheme of the nation. Mr. A. S. McWilliam, acting headmaster of Lady Manners School, Bakewell, started the discussion with an account of the agricultural 'bias' which has been imparted to the teaching of boys and girls over fourteen years of age in his school. After a good general education in the earlier years, the child is given the choice of grouped subjects, but biology is a compulsory subject for both boys and girls. The biology is divided into three sections, plant biology, animal biology and soil science. The teaching is made as experimental as possible, and agricultural plants, etc., are used as examples. Bees, a demonstration orchard and school clubs form an important part of the system.

Mr. McWilliam said that the bias was introduced in 1920 with the object of making the science course more attractive, improving the examination results, and encouraging the parents to leave their children longer at the school. The object is not to teach boys and girls farming, but to make use of the country way of life in teaching the principles of science. At the same time it was hoped to create in the minds of the children a better understanding of the importance of the fertility of the soil, the biology of the mammal and the principles of nutrition. Both the laboratory and outside work are arranged on the heuristic system whereby the child is allowed to discover some elementary facts by itself.

Dealing with the objection raised in some quarters that the teaching of agricultural science in the secondary schools will not give an adequate grounding in science for the student, who enters an agricultural college or university, Mr. McWilliam said that at Lady Manners School this has not been found to be the case. Boys and girls have gone forward to the universities and colleges and have been as successful as those from other schools. He is convinced that the agricultural bias in the secondary school after the age of fourteen creates a wider outlook, a greater interest in school work and a better understanding of the countryside. But if the schools are to encourage boys and girls to take up agricultural careers, they must be assured of a decent livelihood in circumstances where the amenities are equal to those of the town; to attain this we must have a prosperous countryside able to pay good wages and offer good prospects to the best boys and girls.

Mr. J. Hunter Smith, principal of the Hertfordshire Farm Institute, in speaking of the farm institute as an introduction to adult education, not only gave a detailed educational programme but also strongly stressed the need for non-vocational or cultural subjects in the curriculum. He advocated the establishment of Young People's Colleges in rural districts, equipped with appropriate workshops, where the part-time student could get further education through hand and eye rather than by lecture and book. At the farm institutes he hopes that there will be a new approach to technical instruction by linking it more intimately with living or moving examples and activities, for there is something dead and uninspiring in transcribing notes on breeds of livestock, varieties of cereals and all the dry data that are so frequently provided. He wants the principle of farm management to be absorbed rather than taught, through continual field observation and the study of records.

In Mr. Hunter Smith's opinion, it is extremely important that non-vocational subjects should find a definite and prominent place in the syllabus of every farm institute. It is a mistake to relegate this basic branch of adult education to occasional debates, discussions or special lectures in the evening. The first lecture hour in the morning would be the ideal. That hour would represent just a little of the idea which has borne such bountiful fruit in the Danish high school.

With regard to the demand for training in agriculture that will arise when the Services are demobilized, Mr. Hunter Smith suggested that the first step should be a period of some months up to a full year as a 'working guest' on a suitable farm. Thus by work on the land, and especially by fireside talks in the farm-house, these men would learn what it all means in respect of both work and prospects.

The first of the technical papers to be read was contributed by Dr. John Hammond, on "The Breeding of Cattle for Milk or Meat". He pointed out that the supremacy of British farmers in methods of breeding for beef is based on visual judgment and touch of the animal. These methods are of little use in the breeding of cattle for milk and butter-fat yields, unless they are coupled with complete production records extending over a number of generations. This is probably the reason why we have not attained that supremacy in breeding for milk that we have in beef production. A great extension of milk recording is still required. Unfortunately, milking qualities cannot be measured directly in the bull, and since each year he may contribute thirty-five calves or more to the next generation while the cow produces rather less than one, the importance of paying attention to the bull when breeding for milk is obvious. Dr. Hammond advocated a system of breeding from "proven" bulls similar to that which has given such striking results in Holland, the United States and Denmark in recent years in breeding for milk and butter-fat.

Dr. Hammond is of opinion that we can obtain

only a small proportion of our beef from pure beef herds; the bulk of our beef must be obtained from dual-purpose cattle or from these crossed with a beef bull. To obviate the danger that heifers from this cross may find their way into dairy herds and so reduce the efficiency of the dairy industry, he advised the use of beef bulls having a distinctive colour marking, such as the Hereford (white face) or Aberdeen Angus (black colour), which are dominant genetic characters and so colour-mark their offspring with a trade mark for beef.

A plan for the organization of machinery instruction within the county education framework was outlined by Mr. D. I. McLaren, who contended that the facilities available for obtaining advice on agricultural engineering problems have not kept pace with those provided for the other branches of the industry. Among other recommendations he suggested the inauguration of an advisory service, partly within the county under the charge of a suitably trained man with the status of assistant county agricultural organizer, and partly on a provincial basis, with an adviser in agricultural engineering on the lines of the existing advisers in chemistry, economics, etc.

Mr. C. Davies put in a plea for the reduction of types and varieties of farm machines on the grounds that many of them are not really necessary. He said that the War has taught us to do without many things in ordinary life which were previously considered necessities, and many tools which formerly were considered useless unless of a very exact shape are unobtainable to-day; but we shall find that other shapes do just as well and sometimes even better. In the case of the plough, of which very many types exist, he said that the demands for a particular shape or type are often due, not to a profound knowledge of what the soil requires, but to local custom or prejudice. The same holds good for other farm implements and machinery. Mr. Davies said that it is not in the farmer's own interest to ask for an unnecessary variety of implements, because the fewer the number of different shapes and types a manufacturer has to turn out the lower the costs, and the lower the charge to the farmer. The farmer of the future will have to be more machine-minded, remarked Mr. Davies; no factory can afford to abuse the mechanical equipment it has installed to the same extent as happens on so many farms, and continue to pay dividends. In the discussion on this paper, it was pointed out that the farmer is not entirely to blame in failing to protect his machinery from the weather; the great shortage of suitable farm buildings puts him in a very difficult position, especially now that new construction is limited because of shortage of materials.

IMPROVEMENT OF LIVESTOCK

PROF. ROBERT RAE, of the University of Reading, contributed a valuable address on the improvement of livestock to the proceedings of the National Veterinary Medical Association of Great Britain and Ireland (*Vet. Rec.*, **55**, 429; 1943).

During the War, he said, millions of acres of land have been ploughed up and there have been tremendous increases in crops which can be consumed directly, such as potatoes, barley, wheat, sugar beet and so on. Before the War Great Britain imported ten million tons or so of feeding stuffs for farm animals at a cost of about fifty million pounds a year. Producers of pigs, poultry and milk were most dependent on this, sheep farmers were least so. As the War decreased the shipping available for these imports, first priority in imported foodstuffs was given to dairy cows and milk production, while pigs and poultry came last, because they are almost entirely dependent on the concentrated foods which are largely imported. At the present moment the numbers of our dairy cows have been maintained, with a small increase, but beef cattle and sheep have been reduced to some extent. At the same time our large livestock population has built up reserves of soil fertility which has helped our crop production.

Prof. Rae thinks that livestock production must remain after the War the predominant feature of British agriculture. We shall need fresh (perishable) agricultural products; large areas of Great Britain are not suitable for intensive arable cultivation, although much of this land can be improved; even in our arable areas there is much land which cannot without the fertilizing power of livestock upon it be kept in what the farmer so graphically and beautifully calls 'good heart'. Prof. Rae does not advocate the return of large areas to permanent grass. He thinks that the war-time policy of temporary pastures, endorsed by generations of Scottish farming, should be continued after the War. They give fresh, clean pastures and should give increased stock-carrying capacity and the opportunity of using the fertility accumulated by the livestock. This system of temporary leys has been introduced by the County War Agricultural Committees much more quickly than it could have been introduced in normal times.

Prof. Rae thinks, however, that we do not produce enough food for even our pre-war numbers of livestock. We ought to revert to our pre-War numbers of livestock or to increase them, and, if we do, we shall need imported foods again after the War. Further, Great Britain has often been called the stud farm of the world. The best herds and flocks of many other countries, of the Dominions Overseas and of North and South America were founded on stock supplied by Great Britain, and our pre-War trade in breeding stock was valuable. We could, indeed, be proud of our breeding stock; but we could not be satisfied with a good deal of our ordinary stock in the fields. The level of all livestock in Great Britain needs to be raised; more farmers should attempt the difficult job of breeding. More breeders and fewer mere multipliers of stock is, in Prof. Rae's opinion, a sound maxim for the future.

The rest of his address develops this theme by interesting and valuable summary and comment upon some of the schemes which seek, at present, to improve dairy cattle and pigs in Great Britain. How many people, one wonders, when they get their loaves and bacon and bottles of milk, are aware of the vast organization, the immense labours of mind and muscle and the complex organization and machinery which combine to deliver them at their doors? More than one book has been written about the marvellous organization which delivers at our doors the daily newspaper; and marvellous that organization is: but how much greater, how beneficent and how poorly appreciated are the miracles daily done on the English farm.

Among contributors to the instructive discussion which followed this address were Colonel E. M. Curley, chief veterinarian, European Theatre of Operations, United States Army, and Dr. Tj. Bakker, who gave interesting accounts of some aspects of veterinary work in the United States and Holland.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Saturday, January 22

BIOCHEMICAL SOCIETY (at the British Postgraduate Medical School, Ducane Road, Shepherds Bush, London, W.12), at 11.15 a.m.

INSTITUTE OF PHYSICS (ELECTRONICS GROUP) (joint meeting with the MIDLAND BRANCH of the INSTITUTE OF PHYSICS) (at the University, Edmund Street, Birmingham), at 2.30 p.m.—Discussion on "Space-Charge and Noise in Radio Valves" (to be opened by Dr. P. B. Moon and Dr. R. R. Nimmo).

Monday, January 24

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 5 p.m.—"The British Arctic Air-Route Expedition, 1930–31"; Geographical Films with Commentary by Members of the Expedition.

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Discussion on "Industrial Applications of Radio-Frequency Methods of Heating" (to be opened by Mr. N. R. Bligh).

Tuesday, January 25

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 1.30 p.m.—Miss Olive Lodge: "Folk Festivals in Jugoslavia".

INSTITUTION OF BRITISH AGRICULTURAL ENGINEERS (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Prof. D. B. Johnstone-Wallace: "Mechanisation of the Family Farm".

ROYAL SOCIETY OF MEDICINE (at 1 Wimpole Street, London, W.1), at 4.15 p.m.—Dr. Donald Hunter: "The Clinical Approach to Industrial Medicine".

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, Westminster, London, S.W.1), at 5 p.m.—Mr. H. D. Morgan: "Wharves on Soft Foundations".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Prof. H. D. Kay: "Modern Developments in Dairy Science". i. "Milk and Milk Products as Foods".*

Wednesday, January 26

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. R. N. Armfelt: "Education To-day and To-morrow", 3: "Primary Schools".

PHYSICAL SOCIETY (COLOUR GROUP) (in the Physics Department of the Imperial College, Imperial Institute Road, London, S.W.7), at 2.30 p.m.—Dr. T. Vickerstaff: "Some Difficulties encountered in applying the Theory of McAdam's Limiting Brightness to Real Dyestuffs".

Thursday, January 27

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Sir Lawrence Bragg, F.R.S.: "The Strategy and Tactics of Crystal Structure Analysis by X-Rays".*

ROYAL SOCIETY OF MEDICINE (at Manson House, 26 Portland Place, London, W.1), at 4 p.m.—Dr. W. Norwood East: "Criminal Responsibility and Medical Culpability".

BRITISH INSTITUTION OF RADIO ENGINEERS (at the Institution of Structural Engineers, 11 Upper Belgrave Street, London, S.W.1), at 6.30 p.m.—Mr. F. E. Lane: "Special Electron Tubes".

Friday, January 28

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5 p.m.—Sir Harold Spencer Jones, F.R.S.: "Measuring the Sun's Distance".*

INSTITUTION OF MECHANICAL ENGINEERS (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Prof. G. S. Baker: "Fundamentals of the Marine Screw Propeller" (Sixteenth Thomas Lowe Gray Lecture).

Saturday, January 29

ROYAL PHOTOGRAPHIC SOCIETY (SCIENTIFIC AND TECHNICAL GROUP) (at 16 Princes Gate, South Kensington, London, S.W.7), at 2.30 p.m.—Symposium on "Microdensitometry and Microsensitometry"

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

HEADMASTER of the Junior Technical School—The Principal and Clerk to the Governing Body, Wigan and District Mining and Technical College, Wigan (January 27).

EDUCATIONAL PSYCHOLOGIST (full-time)—The Secretary for Education, Education Offices, York (January 28).

ASSISTANT MASTER to take ADVANCED MATHEMATICS as the main subject and PHYSICS as a subsidiary subject, and an ASSISTANT MASTER to take MECHANICAL AND ELECTRICAL ENGINEERING SUBJECTS—The Principal, Enfield Technical College, Queensway, Enfield, Middlesex (January 28).

SPEECH THERAPIST to serve the Crewe and Cheshire Education Committees jointly—The Director of Education, Imperial Chambers, Prince Albert Street, Crewe (January 29).

HEAD OF THE ENGINEERING MANUFACTURE AND TRADES COURSE SECTION of the Department of Mechanical Engineering—The Principal, Central Technical College, Suffolk Street, Birmingham (January 31).

HEAD OF THE MINING DEPARTMENT at the North Staffordshire Technical College, Stoke-on-Trent—The Clerk to the Governors, Education Offices, Town Hall, Hanley (January 31).

ORGANIZER OF AGRICULTURAL EDUCATION to the East Suffolk County Council Education Committee—The Secretary for Education, County Hall, Ipswich (February 1).

PRINCIPAL of the Gloucestershire College of Domestic Science and Training College—The Secretary, County Education Office, Shire Hall, Gloucester (February 5).

DEMONSTRATOR (man or woman) in the Department of Zoology—The Secretary, Bedford College for Women, Regent's Park, London, N.W.1 (February 5).

QUALIFIED ENGINEER for the development of Light Alloys, their utilization in fabricated form, the investigation of technical problems arising out of current applications and research into new applications, in the North-Western Area—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. C.1962.XA) (February 5).

HEAD MASTER—The Clerk to the Governors, Sir Joseph Williamson's Mathematical School, 116 High Street, Rochester (February 12).

UNIVERSITY LECTURER IN ANTHROPOLOGY—The Secretary of the Appointments Committee, Faculty of Archæology and Anthropology, Museum of Archæology and of Ethnology, Cambridge (April 15).

WORKS ENGINEER for Non-Ferrous Metal Producing Plant in South Wales—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. C. 1944.XA).

HYDROGRAPHICAL SURVEYORS for the Basrah Port Directorate, Iraq—The Ministry of Labour and National Service, Appointments Department, Sardinia Street, Kingsway, London, W.C.2 (quoting Reference No. O.4862.S.).

ASSISTANT PHARMACIST for the Tanganyika Territory Medical Department—The Secretary, Overseas Manpower Committee, Ministry of Labour and National Service, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. 1218).

MATHEMATICS MISTRESS (honours degree) at the English High School, Haifa—The Secretary, Jerusalem and the East Mission, 8 St. Thomas Street, Winchester.

Two full-time ASSISTANT TEACHERS for (a) SCIENCE and/or MATHEMATICS; and (b) GENERAL TECHNICAL SUBJECTS including WOODWORK or METAL WORK—The Principal, County Technical College, Stoke Park, Guildford, Surrey.

LECTURER IN MECHANICAL OR ELECTRICAL ENGINEERING, and a SCIENCE LECTURER—CHEMISTRY and/or PHYSICS, with subsidiary Mathematics, at the Swansea Technical College—The Director of Education, Education Department, Guildhall, Swansea.

ASSISTANT CHEMIST and an ASSISTANT PHYSICIST—The Director of Research, Linen Industry Research Association, The Research Institute, Lambeg, Co. Antrim, Northern Ireland.

COLONIAL RESEARCH AND DEVELOPMENT

THE Colonial Research Committee appointed in June 1942 to advise on the expenditure of the £500,000 a year provided by the Colonial Development and Welfare Act, 1940, for the promotion of research and inquiry in matters affecting the Colonies and to advise upon and co-ordinate the whole range of research in the Colonies, has now presented a progress report on its first year's work, 1942–43*. The report includes an account of developments leading to the establishment of the Committee, the functions of which were outlined by Mr. Harold Macmillan in a statement to the House of Commons on April 28, 1942 ; the first interim report of the Colonial Products Research Council, constituted under the chairmanship of Lord Hankey in January 1943, is appended (see p. 133 of this issue), together with lists of Colonial agricultural institutes, medical research institutes, schools of medicine and veterinary research stations, centres for the collection, distribution and interchange of scientific information on agriculture and medicine, supported jointly by all countries of the British Commonwealth, and particulars of research schemes under the Colonial Development and Welfare Act, 1940, prior to the establishment of the Committee. The report of the Colonial Research Committee is signed by Lord Hailey as chairman, and it is proposed to present an annual report in April in future, that is, at the end of the financial year.

This first report shows an outlook which in itself indicates how wise was the decision to establish the Committee. and also the immensely important contribution to Colonial development and welfare which the Committee will be able to make if adequately supported. The preparatory work described in the Report shows that the Committee has started on the right lines. It has already indicated certain general features of Colonial research that require early attention, and the wide view of its functions taken by the Committee should be all the more fruitful when, after the War, the prosecution of extended schemes of research becomes possible.

The Committee accordingly has not limited itself to the examination of proposals laid before it by Colonial Governments or by other bodies. It has conceived it as its duty to study the whole field of scientific inquiry ; to distinguish the parts of it requiring attention, and to ensure that gaps in it are filled wherever possible. In accordance with this conception of a planning commission for the whole field of Colonial research, the Committee has first limited itself to a preliminary survey of the special problems and needs of Colonial research as a whole, and to an examination of the general principles which should be followed in its organization. Comprehensive planning of future developments now will enable the Government the better to put schemes of research into operation as soon as scientific men and others now engaged in war duties are free to participate in Colonial development.

* Colonial Research Committee. Progress Report 1942–1943. (Cmd. 6486.) Pp. 12. (London : H.M. Stationery Office, 1943.) 6*d*. net.

Naturally enough, the Committee has not yet been able to complete its survey of the major subjects which must come under its review. Its first task has been to form an estimate of the character of the research work already undertaken in the Colonial territories. On this point the Committee, while impressed with the efforts that have been made by research workers in these territories, often in the face of great difficulties, and with the value of many of the results achieved, is convinced that scientific facilities and terms of service must be improved, and new or additional methods of recruitment and organization devised if research is to play an effective part in the development of the Colonies. The isolation of the research worker in the Colonies from fellow-workers in his own, or in kindred, fields of science is one fundamental difficulty. Again, in some Colonies, the shortage of technical staff has obliged research workers to give much of their time to routine work, and even if they are freed from the pressure of routine work, there is a tendency for research problems to be defined too exclusively by local and temporary interests, without due regard to scientific possibilities, or to the scale on which a given investigation must be planned if it is to have any reasonable hope of success.

Under such conditions there will always be difficulty in attracting the ablest research workers to the Colonies, and the Report rightly stresses the necessity of obtaining men and women of outstanding ability in order to make Colonial research effective. To meet these difficulties, the Committee recommends, first, that further attention be given to the special conditions of service of research officers. Of these, the most important is greater freedom of exchange between universities and institutes in Great Britain, in the Colonies, and in other countries where similar research problems are being studied. Study-leave would mitigate the isolation of the Colonial research officer, but by itself is not enough. The Committee suggests that it is worth considering the possibility of establishing separate research services under some central organization in the United Kingdom, possibly the Colonial Office, which would provide a pool of scientific workers on which Colonies could draw.

Both this proposal and the allied suggestion of the formation of a sort of 'scientific volunteer reserve' of workers normally employed in independent institutions reflect the spirit which has animated the recent proposals for the reform of the Foreign Service, but their implementation will involve attention to such conditions of service as salary scales, pensions and the like, and the elimination of anomalies. Equally, they cannot be considered in isolation from the discussion of the status and remuneration of the research worker generally, which has been initiated by recent reports on industry and research. Colonial research, whether from the point of view of staff or organization, must, in the final issue, be planned as part of an imperial policy of research.

A second means suggested by the Committee of mitigating the isolation of the research worker in the Colonies is the development of centres of research and learning in the Colonies themselves. The Committee has been in touch with the Higher Education Sub-Committee of the Advisory Committee on Education in the Colonies, which has been studying the possibilities of developing facilities for research in such bodies as the Universities of Malta, Jerusalem, Ceylon and Hong Kong, and institutions which may prove to be the nuclei of future universities, such as Raffles College at Singapore, Makere College in East Africa, and Achimota and Yaba Colleges in West Africa. An increase in research facilities at these centres would raise the standard of learning in these nascent universities, and do much to remove the sense of isolation at present inseparable from Colonial research.

In regard to the organization of research, the Report emphasizes the need for an extended range of research. The investigations so far undertaken have been directed mainly to subjects involving problems of immediate importance. Commercial undertakings have played a large part in the development of research which has been of direct interest to them. Inquiries of great importance have probably been postponed because they do not fall within the purview of the main Colonial departments, and basic surveys, either topographical or geological, do not exist in many Colonies. Few systematic studies of the flora and fauna of Colonial areas have yet been undertaken, and more detailed investigations of the species of fish living in local waters and their life-histories are indispensable for the further development of fisheries in the Colonies. Ethnological and linguistic surveys are lacking in some areas, as well as data on social and economic conditions, and much remains to be done in the field of vital and census statistics.

For such reasons the Committee considers that an important use of the funds now available will be the extension of the scope of investigations to be undertaken in the Colonies, especially in the poorer territories. By making it possible to organize long-term and short-term basic surveys and to promote research on general environmental problems as well as in the whole field of social research, the new financial provision should do something to meet a further difficulty encountered in the past in the lack of continuity of research. Full value cannot be obtained from research unless continuity is ensured, and one of the main advantages of the new provision of funds under the Colonial Development and Welfare Act is to secure such continuity.

Next, the Report points to the need for central and regional organization, not only to achieve the most economical use of the slender resources of research workers and equipment available, but also as the easiest way of securing that co-ordination between the different fields of research which is necessary if comprehensive investigations are to be made of specific problems, especially those related to development programmes. Machinery for securing the co-ordination of different types of research is particularly important at the present stage of development of the Colonies, and it is well to remember that the frontiers of scientific research do not coincide with political boundaries. Co-ordination of work to be carried out jointly in several Colonies or in Colonial

territories and those of neighbouring Dominions or of other States may be necessary; but in discussing the question of Government control of Colonial research, the Committee emphasizes the necessity of seeking the greatest elasticity in the organization of research. Generally, it should be so organized that Government investigations and those conducted by academic or other bodies go on freely side by side.

In addition to these general conclusions, the Committee has reached a number of conclusions in regard to particular fields of research so far surveyed. The Committee accepts the proposal of the Colonial Survey and Geophysics Committee that topographical and geodetic surveys should be planned by a central Colonial survey organization, and recommends the preparation of a detailed scheme for such an organization, so that the necessary plans can be put into operation at the end of the War when men should be available. Similarly, it recommends the preparation without undue delay of detailed proposals for an extension of Colonial magnetic and meteorological services, in view of their importance to mining developments, to agriculture, and to wireless transmission and radio navigation. A scheme of this kind is also being considered by the Colonial Survey and Geophysics Committee.

The Committee's review of the facilities for forestry research has led to the conclusion that the central organization of Colonial forestry research is already adequately provided by existing organizations, but regional centres will be necessary in the Colonies for research into forest products, and in most Colonies the staff concerned with entomological research and sylviculture should be considerably increased. The importance of research into the systematic classification of Colonial fishes and the study of their life-histories has already been indicated, and, stressing the economic importance of Colonial fisheries and its bearing on nutrition, the Report also points to the need for investigations into methods of fishing, of preserving and processing fish, as well as on the marketing and transport of supplies. For this purpose further marine fisheries research stations are required, especially in the West Indies, West Africa and East Africa. In addition to extension of the existing fisheries departments of Ceylon, Malaya and Hong Kong, establishment of a regional research station for freshwater fisheries in East Africa is suggested.

The Committee received a survey of the present position of agricultural research in the Colonies approved by the Advisory Council of Agriculture, Animal Health and Forestry, and reviewed the progress in the organization of agricultural research since the recommendations of the Imperial Agricultural Research Conference in 1927 and the two Lovatt Committees on Agricultural Research and Administration in the Colonies in 1927 and 1928. It is considered essential that research work on a full scale should be resumed at Colonial centres as soon as possible, with such measures of reorganization and extension as may be necessary to cope with post-war development. In addition to further provision of staff and facilities for research on the cytological side of plant genetics, on plant physiology with special reference to plant disease, on virus diseases of plants, and on trace elements, on the control of insect pests by biological means and by the use of insecticides, and on insect pests of stored products, etc., the importance of planning agricultural research in line with modern views of agricultural policy as reflected in the pronouncements at the United Nations Conference on Food and Agriculture at Hot Springs is stressed. A policy of raising the standard of living of Colonial peoples and particularly their standards of nutrition involves co-ordinated schemes of land utilization surveys, forestry research, experiments in methods of improved cultivation in backward areas by the introduction of better strains of crops and mixed farming systems suitable to local conditions, improved storage, grading and marketing and a co-ordinated policy for improving human and animal nutrition; for such planned development the closest interdepartmental co-ordination will clearly be necessary.

While medical research has not been considered by the Committee in any detail, its survey of the position of veterinary research has led to agreement that regional research centres in animal health are required for each group of territories, with, if necessary, separate laboratories for the production of biological preparations. Each Colony should also have a small laboratory for the study of its own local problems and its own pathological work. Again, while in the initial stages veterinary research in the Colonies should be directed towards the control or elimination of the most destructive diseases of stock, this must be followed by research directed towards the improvement of livestock with a view to the maintenance of healthy and productive herds to supply the nutritional and economic needs of the Colonial peoples. For this purpose, research on animal health requires organization on a wider basis, and the inquiries involved will call for the co-operation of teams of workers in different scientific fields.

Finally, in regard to the neglected field of the social sciences, in the absence of appropriate organizations, the Committee has sought the advice of groups of experts in linguistics; demography, anthropology, and social surveys; economics; systems of colonial law; colonial administration; and education and psychology. The organization of research in the social sciences will be considered further on the basis of the reports of these groups. The Committee is also taking every opportunity of establishing contact with interested individuals and organizations in other countries, and particularly with those within the British Commonwealth. It has also recommended the establishment of Colonial research fellowships, so as to build up a cadre of young men and women familiar with colonial scientific problems and able to help in their solution; and it may be of value to finance occasional pieces of research by senior scientific workers holding academic or other research posts.

There can be no question as to the importance of the work to which the Colonial Research Committee has addressed itself, both from the point of view of implementing the new colonial policy and realizing

the hopes aroused by the Hot Springs Conference. It has a close bearing on the whole question of world trade and full employment policy, and the Committee rightly makes it plain how closely the first steps are dependent on man-power. This Report deserves not only the close attention of scientific workers but also careful study by all those bodies concerned with demobilization, such as the interdepartmental committee under Lord Hankey to ensure the relation of training and educational facilities to prospects of employment at home and abroad and to university development and reorganization. The basic problems of colonial research and their implications are fairly stated, and scientific workers must not shirk the responsibility of seeing that the appropriate action is taken or of facilitating the difficult task of securing the large amount of co-operation which in such fields as agriculture and animal health is as indispensable a condition of scientific as it is of social and economic advance.

THE HOUSE OF MACMILLAN

The House of Macmillan (1843–1943)
By Charles Morgan. Pp. xii+248. (London: Macmillan and Co., Ltd., 1943.) 8*s*. 6*d*. net.

IT was on November 10, 1843, that two young Scottish booksellers, Daniel and Alexander Macmillan, published their first book, "The Philosophy of Training", by A. R. Craig, late classical master in Glasgow Normal Seminary. They were setting up a bookselling business in Cambridge (now that of Messrs. Bowes and Bowes), but they had other ambitions, "to realize some of their ideals" by publishing good books—and their London office at 57 Aldersgate Street was the first step towards their establishment as one of the greatest of publishing firms. Both had youthful experience with booksellers and publishers, and in the main had educated themselves; but they made the acquaintance of Archdeacon Hare, and through him of F. D. Maurice; in Cambridge, customers, young and old, became friends, with lasting respect and affection, and their rooms became a centre of serious discussion, social and theological. Alexander did much for the Working Men's College in Cambridge; Daniel defended Maurice in private and in public. Meanwhile, authors multiplied and books appeared, some of them still in service, such as the translation of Plato's "Republic" by Davies and Vaughan. Of the early authors, best known are Charles Kingsley, and Tom Hughes, whose "Tom Brown" had immediate success. Daniel had never been strong, but his wise counsel was a mainstay until his early death in 1857; and one of his projects, the London branch at 23 Henrietta Street, Covent Garden, was realized soon after, with a similar club-like appendage, where 'Tobacco Parliaments' attracted an increasing number of guests—poets, historians, men of science, and story-tellers, among them Tennyson, Huxley, Dicey, Palgrave, and Herbert Spencer.

These were the notable beginnings of an enterprise which has more than justified them. The story of it is a remarkable cross-section of the literary and intellectual world of the Victorian age, so strenuous and serious in pursuit of many divergent aims, but behind its colossal gravity so intensely human. There is a distinction in degree, rather than in kind, between biography and history; and when biography deals with a family, and with two or three generations, as here and in the recent "Time and Chance" of Dr. Joan Evans, the distinction begins to fade. When it also deals with a corporation, and with the profession which it subserves, it almost disappears, unless the personalities are unusually forcible and congenial. On the other hand, the more significant the narrative, as an illustration of contemporary notions and trends, affecting those persons as well as affected by them, the closer does the work come to strictly historical writing. Few recent books have given so vivid and wide a glimpse into the cultivated life of London during the last hundred years, or brought so many portraits into one 'conversation piece' describing the setting of their common interests and pursuits; or analysed so critically the institution which interconnected them, as well as the persons who created and maintained this common bond; the combination of business ability, critical judgment, and personal humanity which gives a publisher's life its opportunities and its rewards, in fame and in friendship.

Being eminently business-like men, the Macmillans have kept ample record of their doings, their experiences, and their thoughts; and Mr. Morgan has evidently had liberal access to these archives; even in Daniel's frequent absences through ill-health, Alexander's copious correspondence with him preserved unusually intimate detail for the earlier years. As their business grew, they all became more dependent on critical reports from trusted and experienced advisers, among whom John Morley was the most eminent, and is the most often quoted. Later, the long memories of loyal retainers add picturesque detail and wholesome atmosphere to the written records: good masters are well served. But it is clear that many important decisions were taken on personal impressions of one or more of the partners, as well as on their reading of manuscripts. Especially was this so in early days, when authors like Maurice, Kingsley and Hughes were their personal friends, and others, afterwards famous, were the contemporaries or the juniors of the head of the firm, himself still in the forties. That is the significance of the letters quoted here, to men like Hardy, or Rossetti, or Watt; of the design on the cover of so many Macmillan books—"the stars for heavenly light and glory, the acorns for earthly growth and strength, the tree for useful industry, the butterfly for beauty pure and aimless"; of the invention—for it was no less—of the "Golden Treasury", the "Globe Shakespeare" and its companions, and the "English Men of Letters" series. As Mr. Morgan writes of publishing generally, "its character certainly, and perhaps even its romance, may be more truly said to arise from its sharp intermingling of calculation and industry with intuition and mere chance". In no calling does so much depend, as in publishing, on the character and judgment of the publisher.

On more than one occasion, by its grasp of principle and obstinate adherence to policy, the house of Macmillan rendered public service to everyone concerned in the production and distribution of books. Of these the most important in retrospect were the discussions of literary copyright, from Alexander Macmillan's letter to Sir John Coleridge on July 30, 1873, to the new Copyright Act of 1911, in the framing of which Frederick Macmillan had a share; the Net Book Agreement between the publishers and

the booksellers achieved after long negotiations in 1899; and the consequent 'Book War' with *The Times* Book Club in 1906–8, in both of which he was again in a leading part. Now that this ferocious struggle is long over, it is possible to put the whole matter in an impartial and historical way, and Mr. Morgan has done this well.

Another great service was the publication of English classics, and also modern books such as Morley's "Life of Gladstone" in popular but well-printed editions for a few pence a volume or part. It takes its place in the same historical perspective as the University Extension Movement, and the copious supply of elementary text-books by first-rate authorities, especially in classics and in natural science, for a new and very wide public in the secondary schools. Mr. Morgan gives examples of the great care taken personally by members of the firm, and especially by Maurice Macmillan, in the selection and—one may almost say—the training of authors, in this important branch of literature.

Very fortunately, as its business widened, the House of Macmillan was able to supply within the family circle a succession of able men, each moreover with a contribution of his own. In the general conduct of affairs, Frederick Macmillan's versatile and thorough acquaintance with the technique of printing and bookselling, and his long residence and family ties in North America, made him the natural successor to his uncle Alexander. Maurice, hard-headed but as fertile in ideas as any of his brothers, "carried the unspectacular but important responsibility of the firm's educational department" already mentioned, and out of this developed the large business with India, which had engaged Alexander's attention long before, on its educational side, and profited by the wise experience of Sir Roper Lethbridge of the Bengal Educational Service. The policy was the same as at home, "to get the very best men in each kind of knowledge to write the most elementary books", but they had to be written to meet Indian needs and conditions, and Maurice's long journey in 1884 was a real contribution to the advancement of education in India.

George Macmillan, a King's Scholar at Eton, who had learned to love Greece with Mahaffy, brought wide unacademic insight into many aspects of classical scholarship, dealt with such portentous growths as Frazer's "Golden Bough" and Arthur Evans' "Palace of Minos at Knossos", founded and long directed the Hellenic Society and (with Walter Leaf) was the earthly providence of the British School of Archæology at Athens, honorary secretary of the Royal College of Music, an active member of the Society of Dilettanti for which the famous "Antiquities of Ionia" were completed at last: and he could take a hand both in Groves' "Dictionary of Music and Musicians" and in the "Cambridge Natural History", examples of the "long-term publishing" characteristic of the House throughout. If his "austerity on duty" was "a little intimidating" to the young, the intense devotion of this precise ascetic-looking Olympian to 'unpractical' but remunerative enterprises was a peculiar stimulus until the man himself was revealed.

Less easy to assign is the responsibility and the credit for the firm's record in the advancement of natural knowledge by many great text-books, and above all by the publication of NATURE. "The risk was not small" and it was nearly thirty years before it "began at last to pay its way" as an "intelligence service" among men of science themselves, as well as for the public. It was its peculiar good fortune to have had only two editors between 1868 and 1938, namely, Sir Norman Lockyer (1868–1918) and Sir Richard Gregory (1918–38) (see also NATURE of February 27, 1943, p. 231), whose eightieth birthday is celebrated on January 29 (p. 133).

It is only possible to select from Mr. Morgan's intimate and congenial retrospect the more conspicuous achievements, and some indications of the principles and policy on which they were based. But it is the humanity, the personal enthusiasms and convictions, which make the record so significant. From the first, the Macmillans "did their best to realize some of their ideals" by publishing good books by the right people. Long may they continue to do so. JOHN L. MYRES.

PSYCHOLOGY OF INTERNATIONAL PEACE

Conscience and Society

A Study of the Psychological Prerequisites of Law and Order. By Dr. Ranyard West. Pp. iv+260. (London: Methuen and Co., Ltd., 1942.) 15*s*. net.

IT is very important that psychologists should play their part in the affairs of post-war years, and especially in the coming attempt to establish international peace on a sure footing. They must show that they have a genuine contribution to make, and that they are capable of making it in a way which can be understood and utilized by people without the psychologist's special training. It must be a clear and simple contribution, to the point and free from disabling controversy. It must show the wisdom and restraint which come from a deep insight into life and experience.

On account of these needs we are grateful to Dr. Ranyard West for his book "Conscience and Society". He has presented, in serious and scholarly manner, arguments which show at least some of the essential factors in the great problem of establishing international peace. There are, in his opinion, two major groups of impulses in mankind which are related to this problem. They are the social and the self-assertive or aggressive instincts. The social or co-operative instinct he believes to be normally uppermost, and it seems to him the main impulse behind our daily comradeship. The aggressive instinct is biologically understandable as providing each individual with the impulses of self-defence and self-assertion; but in his view of human nature, it is more like a reflex occasionally aroused than like an appetite in need of periodical gratification. A third force operates in man's social life, namely, conscience, and this, according to Dr. West, is the fear of the loss of the love of our fellow-men through the self-interested expression of our own assertive and aggressive impulses. This conscience supports the social against the aggressive urge, and helps to preserve peaceful and constructive social relations.

Every individual, however, is liable to outbursts of personal aggression, and those who are neurotic owing to the persisting after-effects of infantile and childish disturbances of emotion are peculiarly liable to such outbursts. Hence external control, government and law are needed to strengthen conscience and enforce its demands in moments of weakness. In this respect groups and nations are comparable with individuals. Their goodwill depends

on circumstance, and their loyalty to ideals of international peace depends on the vagaries of the self-interest of national and sovereign powers.

Thus, in the establishment of world peace, nationalism and the self-interest of sovereign States, which are always potentially aggressive in self-defence, must be given second place to an international organization the function of which will be to control and arbitrate. It must be able to do this without national self-interest, but impartially in the cause of peace, just as, in individual relationships to-day, justice can be carried out with a wisdom which is independent of personal bias and prejudice. Social philosophers, such as Hobbes, Locke, Rousseau and Freud, seem to have viewed man's problems as if reflected by their own personal fears and peculiarities of character. Dr. West points this out and tries to take a truly objective view.

Easy though it might be to criticize Dr. West's book, it would not be easy to destroy its essential meaning. The scheme of two instincts, a 'good' and a 'bad', of which the 'good' is the usual winner, supported by a generally beneficent 'conscience', are excellent as the basis for the exposition of his theme, the importance of which cannot be denied; but this scheme is not sufficient to account for the complexities of life as we know them, and could never form the foundation of social psychology for a deep thinker. The book is overloaded with criticism of other writers, especially Freud, on whom, nevertheless, Dr. West leans very heavily. The shortcomings of Freud's genius are too clear to need such meticulous underlining. The author lays too much stress on the study of obsessional neuroses, and he appears to overlook the part played by psychotic tendencies in group and individual battles and misunderstandings. It seems strange that so experienced a psychologist should think that internal mastery and external control are the only ways of dealing with selfish aggression in group or individual. He does not realize the vast extent to which constructive social life itself depends on the proper use of individual aggression.

These objections, and others which might be made, however, are only asides in a review of so estimable and sincere a work, and can be forgotten in our gratitude to Dr. Ranyard West for giving us a book which is a valuable pointer in one of the directions in which psychology can contribute to the future welfare of mankind. A great merit of the book is that its author has attempted to bring together social philosophers, legal authorities and psychologists in his effort to help in the solution of what must be for them a common problem.

R. W. PICKFORD.

THEORY OF THE TRANSMISSION OF VERY SHORT RADIO WAVES

Microwave Transmission

By Prof. J. C. Slater. (International Series in Physics.) Pp. x+309. (New York: McGraw-Hill Book Co., Inc.; London: McGraw-Hill Publishing Co., Ltd., 1942.) 24s. 6d.

DURING the past ten years or so the published radio technical literature has contained the descriptive results of many investigations into the nature, properties and possible applications of the very short electric waves resulting from the generation of oscillations at frequencies greater than 100 megacycles per second. While the best mode of designating these frequencies and the corresponding wave-lengths is a very controversial matter, one general term is frequently applied, namely, 'microwave'. Any possible misunderstanding as to the scope of the book under review is removed at the start by the author who, in the first sentence of the preface, states that "Microwaves are electromagnetic waves of wave-lengths that we may take, for definiteness, to be between 1 centimeter and 1 meter". It is then pointed out that these waves are unique in the whole range of electromagnetic waves, in so far as the wave-length is of the same order of magnitude as the dimensions of ordinary laboratory apparatus, a feature which makes possible the use of experimental methods differing markedly from those used formerly in radio-frequency technique.

Prof. Slater's book deals with the general principles and fundamental theory underlying the transmission of these short radio waves from point to point, without being concerned with the problems of generation and reception. Microwave problems differ from ordinary circuit problems, in that it is no longer valid to deal with lumped impedances, but thought must be centred on the distribution of the inductances and capacitances around or along the circuit. In addition, conductors in the microwave region are very different from the open-wire circuits used at longer wave-lengths, since such circuits would lose too much energy by radiation to form useful transmission lines. These lines take the form of co-axial cables, consisting of a rod carried concentrically within a hollow pipe, or even of the hollow pipe alone.

From these considerations the book opens with a chapter on the theory of transmission lines, viewed as an electrical network; and then proceeds in Chapter 2 to a discussion of Maxwell's equations, and the production and properties of plane electromagnetic waves. This leads naturally to consideration of the propagation of electromagnetic energy along rectangular wave-guides, and to the general problem of transmission lines when these are hollow conductors. So far the work is confined to the study of disturbances propagated along one definite direction, but when the transmission line or wave-guide terminates in an antenna in free space, the resulting radiation will be emitted in all directions. Chapters 5 and 6 therefore deal with Maxwell's equations in spherical co-ordinates and with the principles of the various directive devices used with antenna systems for very short wave-lengths. The final chapter in the book deals with the coupling of coaxial lines and wave guides, considering particularly the problem of radiation and absorption from a dipole inside a rectangular wave-guide.

Altogether the author would appear to have attained his objective of producing "a book of an intermediate range of difficulty". While an extensive mathematical knowledge is not assumed, some acquaintance with classical electromagnetic theory and Maxwell's equations is necessary, and the work should present little difficulty to the first-year graduate student in physics or electrical engineering, or to the senior worker with a good training in electricity. In view of the extensive application at the present time of the range of wave-lengths covered by the book, this should be found of great interest to many workers and students, even though it does not deal with practical or experimental technique.

UNIFICATION OF BOTANICAL SCIENCE

By PROF. C. W. WARDLAW
University of Manchester

"Botany is the science which treats of plants."
—*Oxford English Dictionary*.

"Every speculation about a single phenomenon wrenched from the continuity of life, is playing indeed a thankless part in the present condition of the natural sciences."—SCHLEIDEN, 1838.

"An unflinching determination to take the whole evidence into account is the only method of preservation against the fluctuating extremes of fashionable opinion."—A. N. WHITEHEAD, 1926.

"An upward outlook is in itself a practical application of any evolutionary view."—F. O. BOWER, 1935.

ANY biological phenomenon can be considered from several different points of view, each of which may lead to the formulation of particular and distinctive concepts. In some instances concepts relating to different aspects may overlap: in other instances they may belong fundamentally to different categories. Now, it is a fact that botanical science has developed erratically and spasmodically; botanists have embraced strange and irreconcilable philosophies; they have welcomed innovations and canalized them into fashions or moulded them into new branches of the science. Moreover, the results forthcoming from the several distinctive phases have not invariably been studied with due regard to their mutual relationships, nor have they necessarily been envisaged as contributing directly to a generalized scheme. The piecemeal character of the scientific advance and the diversity of its branches of underlying philosophy have increased notably during the last fifty years; for it has been a period of great, if non-co-ordinated, activity along many seemingly divergent lines of inquiry. Cogent reasons, therefore, exist for the view that the time is at hand when an effort should be made to achieve some closer integration of the science as a whole.

As a result of the growing volume of research on almost every branch of botany and the concurrence of certain contemporary lines of investigation, there is a reasonable hope that certain gaps that have hitherto hindered synthesis may in due course be bridged and that this may lead towards a real unification of outlook. To some, no doubt, this may appear as unjustifiable optimism. The question may indeed be asked why this topic is considered to merit special attention at the present time. It may be argued that botanical science does not in fact lack unity, that it has been adequately unified at various times in the past, or that complete unification is difficult or even impossible. Moreover the nature of the unification envisaged itself requires elucidation: What kind of unification and for what purpose? I have in mind both the conceptual and methodological aspects: the former is concerned with general questions, that is, possessing significance for the plant kingdom as a whole; the latter considers the results of a particular discipline in relation to those of all other relevant disciplines, instead of such results being treated in comparative isolation. It is this latter aspect of unification that I consider of particular importance at the present time.

It seems evident that failure to achieve some progressive method of integration in the near future will be attended by such an accumulation of non-co-ordinated data as to dismay contemporary botanists and bewilder their successors. There is no novelty in this view, but emphatic reiteration seems timely. In the long view, teaching and research are inseparable; failure to collate the main results of contemporary and past work will certainly militate not only against reasonable advance but also impede the proper teaching of the subject.

In the realm of biological science, where a sense of ever-increasing complexity appears to be the chief reward of the most profound investigations, the less complicated structure and mechanism of plant life, as compared with animal life, might be expected to afford a more direct approach to the fundamental problems of organic Nature. Hence an unbiased observer might take it for granted that botanists would automatically take the lead in the formulation of new concepts and the enunciation of broad generalizations. Reference to some recent works on general biology can scarcely be considered to support this view; indeed, a certain neglect of botanical work is apparent by adherents of other branches of biology. It may be that botanists are to blame; for while collectively their science abounds with new and impressive discoveries, it may be argued that these have not been presented in such a way as to be readily accessible to the general reader. The justification for seeking to co-ordinate the various branches should lie not only in its desirability on philosophic grounds but also in its results. Past prophecy as to the future direction of scientific achievement has not enjoyed such a success as to encourage present attempts, but it seems evident that a period of great synthetic development is on its way. This potential development, however, will only become actual if a synthesis, dynamic and progressive, of all new knowledge is steadily maintained in some reasonably accessible form. Thus a contributory channel of specialized research would be seen not only in relation to neighbouring channels but also to the course of the main stream.

Botany and the Botanists

"Botany is the science which treats of plants" (*Oxford English Dictionary*), and in an extended definition is usually understood to include a consideration of their growth, development and reproduction, the functions of their organs, their origin, systematic affinities, geographical distribution and relation to their environment. Some years ago Prof. W. Stiles indicated that in his view there could be no such thing as a *general botanist*: that an investigator may take a sympathetic interest in other branches of the science and realize the bearing of such work on his own, but that the latter, in these days of specialization, must necessarily lie in one particular field. Clearly in such a statement there is ground both for agreement and dissent. In so far as an investigator fails to realize the relation of his work to the science *as a whole*, so may he fail to appreciate the actual and potential development of the subject in his time.

What, then, do we hope to make of "the science which treats of plants"? What, in particular, is to be the relationship of the specialized branches, for example, plant biochemistry or genetics, to the parent science?

The last five decades have witnessed a great expansion of botanical research in the course of which new aspects, each requiring detailed investigation by means of special technique, have become distinct, specialized and almost separate branches of

biological science. To-day, a botanist tends to be labelled systematist, cytologist, geneticist, ecologist, mycologist, morphologist, palæontologist, physiologist or biochemist, the underlying assumption being that he is that and little else. A further unfortunate consequence of specialization lies in the fact that common ground for discussion becomes more and more difficult to find, and in extreme cases may even lead to the view that it does not, for practical purposes, exist. Although an official cleavage between botanical morphology and physiology was avoided at the British Association meeting of 1894 in Oxford, nevertheless an adequate sense of mutual aid in the common pursuit is still lacking. The morphologist will tell you, with some over-emphasis but not without justification, that when he looks into text-books of physiology in search of information bearing on his own work, he finds that such books can tell him little that he specially wants to know; and the modern physiologist, though not habitually addicted to helping himself by making the fullest use of morphological observations, rather tends to view the professed morphologist as a relic of a former phase of botanical development and as a less adaptable and less inventive scientific man who is still plodding along in an overworked field; moreover, he, too, may complain that morphological literature fails to provide the information he specially requires. So, too, uneasy relationships exist between other and newer branches of the science. Each new aspect that arouses enthusiasm is soon attended by a profuse outpouring of specialized literature, and this, no doubt, must be accepted as being in the nature of things. But several important consequences should not be overlooked. These include: (1) vast accumulations of reading matter which are such that a worker *in any single branch* has to read constantly to keep up to date; and (2) an increased specialization of outlook, which, if left uncorrected, will make for a progressive disintegration of the science as a whole.

Now, no one would desire that specialization in the various branches of botany should cease. Such close investigation of particular phenomena is of the very nature of the scientific method. Indeed, the more facts these branches can produce, the better for biological science as a whole, provided they are made readily available to readers working in other branches. The crux of the problem, then, is this: How is the contemporary *botanist*, conscious of the need *for achieving a full and coherent account of the plant and its life*, to make the best use of the several contributory branches without wishing to deny to them the fullest freedom to pursue their own aims? For two things are certain: (1) no single human being can now hope to read in detail the literature of the several special branches; (2) no particular branch will relinquish its aims or limit its scope for the sake of the mother-subject. Thus it is not a question of re-uniting the several separate branches, or of making any one the hand-maiden of another, but of being able to synthesize or integrate the facts of these branches in the interests of the central aims of botany.

Before attempting to take the matter further, it may be advantageous to consider briefly some selected aspects of the development of botanical science.

Early Developments

It is almost certain that the early systematists, having arranged in orderly fashion the species of plants known to them, must have been conscious of having imparted coherence where none had previously existed. Here it is appropriate to refer to the works of John Ray (1628–1705), of whom Sachs has written that he "not only knew how to adopt all that was good and true in the works of his predecessors, and to criticize and complete them from his own observations, but could also joyfully acknowledge the services of others and combine their results and his own into a harmonious whole". The tribute is deserved, for though Ray's "Historia Plantarum" consists essentially of a series of descriptions of all plants then known, the work is prefaced by an account of morphology, anatomy and physiology as then understood. Later, too, Linnæus, having achieved the completion of his system, must have been conscious of having created a new and desirable unity. Along entirely different lines the German botanist, Caspar Wolff, discussed general questions such as the fundamental nature of the shoot system, and concluded, as stated in his "Teoria Generationis", 1759, that he saw nothing in the plant but leaves and stem. Later, inspired no doubt by Wolff's generalization, Goethe formulated his theory of metamorphosis in which all the various and diverse appendages of the shoot in higher plants were regarded as being the metamorphosed products of a single fundamental organ, the 'ideal' leaf. Here, indeed, the nature philosopher had conferred a unity on the objects of his study, but as Schiller pointed out to him, the abstract conceptions which he employed belonged to the realm of ideas rather than of facts.

The scholastic tradition which prevailed during the first half of the nineteenth century died hard, and botanical science made indifferent headway until Schleiden trenchantly preached a new gospel—that the highroad to new discovery lay in the study of development. It remained for his disciple Wilhelm Hofmeister to show what could thus be done. To view his work in proper perspective it is necessary to realize how very little was then known of the Cryptogams and indeed of the life-history of higher plants. The reproduction and embryology of Bryophytes and Pteridophytes constituted practically an unexplored field, while precise data relating to the development of the embryo-sac, fertilization and embryology in the higher plants were still being collected—all this rather less than a hundred years ago. The contemporary botanical world may well have been astonished when it first read the curious catalogue title of Hofmeister's paper: "Comparative Researches on the Germination, Development and Fruit Formation of the Higher Cryptogams (Mosses, Ferns, Equisetaceæ, Rhizocarpaceæ and Lycopodiaceæ) and the Seed-formation of the Conifers" (1851). It must have appeared as if the wrong things, mosses and gymnosperms, had somehow been run together for comparative treatment. But this was no fallible production, nor was the strange association of data an indication of faulty judgment, for the young German botanist was telling the world that mosses, liverworts, lycopods, equiseta, ferns, gymnosperms and phanerogams all shared a common life-cycle, characterized by the same critical events and developmental phases, and by a recurrent alternation of generations. Here, on a substantial basis of observation, was a synthesis which conveyed a sense of unity hitherto unknown. Later, in 1896, following on the discovery of chromosome behaviour, Strasburger was in a position to announce the further important generalization of the relation between the chromosome-cycle and the somatic-cycle.

Hofmeister's General Morphology

These and other examples which could be quoted afford evidence of the way in which new data and the generalizations which could be based on them not only widened the scope of botanical science but also conferred on it a new sense of coherence. These instances, however, do not convey any adequate idea of the *methodological unification* which I consider to be desirable. For such a discussion the starting-point lies in the works of Hofmeister, for he was not merely concerned with preparing descriptive accounts of changes in form during development, but he also asked himself such questions as: How does the observed form come to be? To what processes of growth can the observed structural developments be related? What internal and external factors determine specific structural organization? The substance of such investigations he described as general morphology. Not only did he consider the problems of form from the physiological aspect, but he also actually carried out physiological investigations. In short, it may be claimed for him that he achieved a view of the whole field of botanical research which, within the limits of contemporary knowledge, could not well have been bettered; with suitable modifications it is one to which we might well aspire to-day.

In introducing his new point of view to a botanical world largely given over to the speculative writing inseparable from the then prevailing idealistic morphology, Hofmeister employed little general argument. Instead of this he set about the task of replacing old conceptions by new ones based on personal investigations. A clue to his general attitude is surely given in the title of his book: "General Morphology of Growing Things" (Gewächse). As Von Goebel has said: "in this book form-relations are presented as conditions of growth. This growth is investigated". Lastly, to round off our impression of the all-round 'compleat' botanist, it may be mentioned that Hofmeister interested himself in the question of variability in plants and, while demanding further studies of the influence of external factors on the conformation of organisms, he attached himself to the Darwinian theory of descent.

The Phyletic Period

As a result of Hofmeister's admirably objective inquiries and of his critical search for relationships between physiological activity and the assumption of specific form or pattern, it might have been thought that botanical science had at length been established on a broad and sure foundation, one in which morphology and physiology were seen to be inseparable aspects of the same theme. But in what has been called the phyletic period—that which followed the publication of Darwin's theory of descent—the details of plant structure, together with such facts as could be culled from the fossil record, were regarded chiefly as providing materials for comparative studies and for the construction of phylogenetic systems. The sweeping success of Darwin's views must surely have indicated to professed phylogenists that whatever comparative investigations they carried out were bound to 'fit in' somewhere, to contribute in some measure to the wonderful edifice of evolutionary theory. The facts of development and the characteristic features of the adult were thus accepted by them as purely morphological concepts, while physiological and causal aspects, though not entirely neglected, received at best little more than passing attention. But as Prof. W. H. Lang pointed out in an important review of the situation in 1915, the problems of general, that is, causal morphology, would remain even if the phyletic history were before us in full. A bad feature of the phyletic period was the tendency of morphologists and anatomists to resort to facile pseudo-physiological arguments regarding the function and adaptive value of structures and organs. Meanwhile physiological research was going on its own way, out of sympathy, or out of touch, with the historic aspirations and interests of morphology.

Organization and Phylogeny

Each of the major phases in the development of botanical science has been characterized by a central idea. Thus in the Linnæan period the *beau ideal* was to know and classify as many species as possible and to add to that number by new collections from all the ends of the earth. In the Darwinian period and after, the problem of descent, which included the construction of phylogenetic systems, was the chief aim, use being made of the natural classifications which had been evolved during the preceding descriptive phase. Since the beginning of the present century, the mechanisms underlying physiological and hereditary processes have constituted leading themes. For contemporary workers in both botany and zoology the processes involved in progressive organization during development are providing problems of great importance and interest.

Now it is evident that organization could be studied as a subject *per se*, without reference to origins. But since all contemporary organisms have come from ancestors possessing greater or less family antiquity, and since the fossil record informs us that notable changes in structure have taken place down through the ages, it is clear that, whatever may be the findings from our studies of organization in contemporary organisms, such findings must also in some way be related or referable to the historic or evolutionary aspect. This, of course, is implicit in the once firmly held view that the ontogeny of any organism is a recapitulation of its phylogeny. It is apposite to note here that the modern study of organization differs from phyletic studies in that it is essentially dynamic in outlook.

The comprehensive viewpoint, therefore, will require that the results of contemporary investigations of plant organization be also considered in relation to the fossil record of past biological events. If an adequate understanding of the factors underlying the organization of living plants can be achieved, a fuller interpretation of the events indicated by the fossil record may become possible, though it can never be absolute. Whether the concepts issuing from contemporary studies of organization will support the criteria of comparison which have been used in the construction of phylogenies or will indicate that they lack validity is evidently a matter of the greatest importance and interest.

Entelechy and Holism

Since Driesch considered mechanistic conceptions of life to be inadequate he introduced the idea of a controlling or ordering principle—an entelechy—which was independent of physico-chemical laws though these were operative in living systems.

In his important work on "Holism and Evolution", General Smuts, too, considers that the explanation of living organisms cannot be purely mechanical and that mechanistic concepts have their place, and

justification only within the wider framework of the integrated unity of the organism. According to him, holism—defined as the "fundamental factor operative towards the creation of wholes in the universe"—is a *vera causa*, that is, a causal factor with a real existence; in the process of evolution there is a definite and fundamental tendency towards the creation of wholes, the results becoming more marked at progressively higher levels of organic development. Thus, if we take a plant or animal as a type of a whole, "we notice the fundamental holistic characters as a unity of parts which is so close and intense as to be more than the sum of its parts; which not only gives a particular conformation or structure to the parts, but so relates and determines them in their synthesis that their functions are altered; the synthesis affects and determines the parts, so that they function towards the whole; and the whole and the parts, therefore, reciprocally influence and determine each other, and appear more or less to merge their individual characters: the whole is in the parts and the parts are in the whole, and this synthesis of whole and parts is reflected in the holistic character of the functions of the parts as well as of the whole".

Whether one agrees or disagrees with the philosophical or biological implications of holism, a valuable service has been rendered to biology by the author's insistence on the essential wholeness of organisms. In the pursuit of researches into particular aspects this integrated unity should not be forgotten.

Contemporary Aspects of Integration

A survey of certain current biochemical, physiological, genetical and morphological investigations suggests that opportunities for achieving a useful integration of data derived from these several branches do in fact exist. Admittedly the number of instances which may be cited is not great; nevertheless they constitute a beginning which may in due course be notably extended.

The marked increase of interest on the part of biochemists in isolating and determining the chemical composition and physical properties of a number of physiologically active substances is likely to prove of great importance in promoting certain aspects of contemporary botanical research. In some instances these substances, which have been comprehensively described as activators, show remarkable specificity in their action on living tissues. A number of these substances have now been synthesized; an obvious development in biochemistry is to synthesize yet others. A considerable number of physiologically active organic substances of known composition, not so far known to occur in Nature, have also been produced. Physiologists, meanwhile, have been attempting to ascertain the metabolic origin and functional relationships of naturally occurring activators. This exacting branch of plant physiology is one in which substantial progress may be anticipated in due course.

The relation of these developments to the work of the morphologist may now be considered. Morphologists are concerned with the external and internal configuration of plants and regard the facts of embryology, the development of new organs at apical growing points and the attendant differentiation of tissues as integral parts of their work. Hitherto they have laboured under a serious handicap in that they have had very few working hypotheses to account for the mechanism underlying the differentiation of new organs or of new tissues. The observed developments have been regarded as characteristic manifestations of the specific hereditary substance, or in some such generalized fashion, but hypotheses relating to the operation and interaction of individual factors have been inadequate or lacking. Hence the purely descriptive nature of much morphological work and the indefinite nature of many of the conclusions based on it. But to-day a fascinating prospect of new possibilities lies before us. For example, it is known that certain substances which the biochemist can isolate or synthesize are more or less directly involved in those all-important initial differentiations of organs and tissues, or in the subsequent growth to the adult condition. Those substances, which apparently exercise a specific morphogenetic effect, have been described by Dr. J. Needham as morphogenetic hormones. Whether or not, in the complex of factors operative in the moulding of an organ, a single substance can properly be referred to as 'morphogenetic' cannot be discussed in detail here; the important fact is that specific structural developments follow on the application of certain substances to plant and animal tissues, provided the latter are in a suitable physiological condition.

Physiologists have not only been exploring the many aspects of what may be described as general cellular physiology, they have also been investigating those difficult problems which are concerned with the movement of substances throughout the plant body. It is now known, for example, that auxins, produced at the apical growing point of the shoot, that is, the region of active formation of protoplasm, become distributed throughout the plant. Important developments ensue, for example, the inhibition of buds, promotion of root development and the progressive enlargement of tissues. Now these several developments provide the materials which the morphologist is competent to investigate and of which he wishes to render an account either in terms of comparative morphology or in explanation of how the organization or configuration observed in the adult comes to be. In short, the biochemical, physiological and morphological aspects are seen to be inextricably linked, and conjoint work is essential to any reasonably adequate account of the processes involved.

Any relationship that can be established between the hereditary constitution of an organism and the possession of those metabolites which are significant in the development of its specific morphology will represent an important advance in botanical science. Here the interests of the geneticist, the physiologist, the biochemist and morphologist become confluent. So far the instances which permit of a co-ordination of data are few in number. They are, however, of great interest, not least because they indicate the possibility of such work being extended.

In an investigation of tall and dwarf strains of maize it has been ascertained (*a*) that the difference between tall and dwarf races is referable to the action of a single pair of genes, (*b*) that the initial production of auxin, an important factor in the growth-expansion of tissues, is approximately equal at the growing points in the two races, and (*c*) that the characteristic dwarfness in one race is due to the destruction of a large part of this auxin by an oxidase not present in the tall race. Here we have a genetical observation relating to an important difference in morphological configuration, which in turn can be assigned to analysable differences in metabolic activity. When precise, co-ordinated data of this kind become cumulative, as they probably will in time, the

information already gathered by morphologists and systematists may well acquire new significance and provide a new viewpoint from which to consider the central and continuous problem of evolution. Admittedly this is looking far ahead, but the goal is much to be desired.

The relation between genes and developmental processes has only recently begun to receive the attention which the subject so evidently deserves. The lack of co-ordinated development in related branches has no doubt been a contributing factor. At present very little is known about the actual physiological expression of a gene—how and where it exerts its influence: it may affect only one step in the process of development or a chain of processes; or it may be involved systemically in every aspect of development. Indeed, it is held to be improbable that any single formula will be found to unify all observations on the connexion between the influence of a gene and its results.

Biological materials in which some well-marked character is known from genetical analysis to be related to a single pair of genes seem likely to prove of great use in attempts to relate genes with developmental processes. In certain annual and biennial forms of *Hyoscyamus niger* it has been shown that if grafts of annual-flowering plants are applied to biennial stocks in their first year, flower-bud development is induced in the latter; and if the vegetative biennial scions are grafted on to annual shoots they are induced to become flowering shoots. The evidence suggests that a substance (or substances), directly or indirectly operative in flower-bud development, has passed from the tissues of the annual to those of the biennial. Now this factor, which is associated in the hereditary constitution with a single pair of genes, is productive of changes which are of profound interest to both the physiologist and the morphologist. Other instances illustrating the same community of interest relate to such characters as the shape and size of leaves, total growth, branching, difference in chlorophyll content, flower size and shape and sterility. In each, the indications are that gene-dependent diffusible substances are involved; in each the materials are such as to call for detailed physiological investigations and are of the kind on which classical systematic and morphological studies have been based.

Here, perhaps, it is appropriate to utter a word of caution. The subject-matter has been treated in such a way as to illustrate how a plurality of distinct branches of botanical science can be focused, to their mutual advantage, on the same phenomenon. But it would be a mistake to assume that the actual operational relationships involved are simple. Behind every change and development lies all the complexity inevitably associated with the multifarious operations of a metabolic system. Hence, while there is a need for simplification so that main issues and essential relationships are not obscured, the innate complexity of the processes involved should not be underestimated. Experience suggests that it is unlikely that any so-called specific morphogenetic substance is as direct in its moulding activity as the words would appear to imply. It is safer to assume that every morphological development is the result of the interaction of many factors.

To summarize briefly. The guiding lines are these: the hereditary constitution of a species, itself a small fragment of the evolutionary picture, is conceived as being subdivisible into genes; these are involved in all developmental processes; they find expression in the action of chemical substances, which in conjunction with temporal, spatial and physical factors are directly or indirectly operative in morphogenetic processes and culminate in the production of the distinctive organization of the adult.

Tissue Culture

An all-pervading consideration in biology is the physiological mechanism relating to the assumption of form, that is, to the origin of the ontogenetic growth pattern and its development to the adult status. How are we to approach this very difficult problem, and how are we to test such hypotheses as may be constructed? What, for example, are the factors leading to the institution of an apical meristem? How is it maintained in its active formative capacity? To what can we attribute the orderly development of leaf and bud primordia? What factors determine their bilateral and radial symmetry respectively and the characteristic shapes into which they are moulded during development? And the overriding 'wholeness' of the organism, what of that? These are questions on which we scarcely know how to make a beginning, for the problems are of a manifold complexity. We note that they involve the origination of cells (cytogenesis) and of organs (organogenesis)—in fact, all that is connoted by the word morphogenesis; but they also involve a great deal more.

One possible line of approach, on which a beginning if no more has been made, is by means of tissue culture. The advances made during the last thirty years in mycological and bacterial cultural methods have played an important part, and media of precise composition can be prepared on which the tissue of certain plants can be maintained in a state of growth without differentiation for an indefinite period. Here then are the means by which it may be possible to determine experimentally, on materials of known genetic constitution maintained under controlled conditions, the direct or indirect action of many factors considered to be operative in morphogenesis. Whether this hope is vain or whether it will, in fact, be realized, remains to be seen.

Conclusion

In this essay it has been quite impossible to refer to all aspects of the unification of botanical science. Studies of plant distribution, for example, which are of interest not only to the systematist, geneticist and ecologist but also to the morphologist and physiologist, have of necessity been omitted from the discussion. So, too, with taxonomy and other important branches. I have attempted to illustrate a point of view, not to cover the field.

To bring out particular points, I have referred to both conceptual and methodological aspects of unification. There are important instances where the two may be closely related. For example, the phylogenist makes use of certain morphological criteria of comparison. The validity of these criteria depends, among other things, on the accuracy of our knowledge of morphogenesis and this, on a further analysis, is seen in practice to require the conjoint work of the biochemist, physiologist and morphologist.

From the multiple-aspect-study of organization during development we not only derive some impression, however inadequate, of the organism as a whole;

we are brought face-to-face with the undeniable wholeness of the organism. A case has been made out for the view that the over-emphasis of any single aspect, while the whole is not kept in proper perspective, will almost certainly lead to the fabrication of unstable theoretical superstructures, destined to crumble because they have not been based on the fundamental reality of organic wholeness. This is a matter which concerns all botanists, though each, according to his capacity, must perform his detailed work in a particular field. But whatever that field may be, he will at one time or another be concerned with some aspect of the distinctive growth-pattern of the organism which he is investigating; this, it need scarcely be said, is of paramount interest to the morphologist at large. An interesting contrast that has been drawn between the 'substance-minded' and the 'relation-minded' man is relevant to the present discussion. "The substance-minded type of thinking," says A. H. Hersch, 1941, "is unquestionably the older, both in the individual and the race. It has all the tenacity of original sin. In morphology it has given us representative particles, preformation, the transmission of acquired characters, and such morphochemical hybrids as bristle-producing, facet-forming substances, and so on. The morphologist, when substance-minded, thinks of the developmental pattern in terms of the visible structural characteristics from stage to stage. In short, he thinks in terms of a series of pictures. But when relation-minded, the morphologist recognizes that the pattern at any moment is the expression of the events which produce it, and attempts to gain a knowledge of the durations and rates, and relative durations and relative rates of the component processes in the developmental nexus. Consequently, instead of thinking in terms of a series of pictures, the relation-minded morphologist tends to think in terms of the non-picturable. If the problem of the developmental pattern is similar to the problems of the more exact sciences, then no doubt in time a system of equations will be developed to facilitate our thinking about it".

There is the modern outlook on *one* aspect of morphology. While it is evident that certain comparative studies and all fossil studies will continue to conform to the older pattern, the new point of view suggests great possibilities for further exploration. The feasibility of pursuing these investigations to a successful conclusion will in large measure be determined by the existence of the tools to do the job. Some of these are already at hand. Here I have in mind certain major biological works recently published or re-issued, for example, D'Arcy Thompson's "Growth and Form" (2nd edn.), Needham's "Biochemistry and Morphogenesis" and Child's "Problems of Pattern and Development". Each tends to emphasize a particular aspect, but taken together they afford both the morphologist and physiologist a working knowledge of the several biochemical, physical, physiological, temporal and spatial factors which, at one or another stage of development, may be operative in moulding the distinctive form of the organism.

The publication of a major work, such as any one of those mentioned above, or of a first-class text-book, is an event of rather occasional occurrence, and depends on particular individuals who possess the experience, capacity and urge to attempt a synthesis. Now, the point of view conveyed in Hofmeister's general morphology, with appropriate modernization and thereafter subject to progressive integrated development, would appear to represent a desirable central aim in botanical science with which few would disagree. With this as a focal point, it is cogent to inquire how we are to make the best use of the data of each of the special branches, having in mind the volume of such literature, the present tendency of individual workers towards intensive research in a restricted field, the fact that this may involve disability to broader vision, and the finite mental capacity of human beings. It is undeniable that the proper comprehension of the subject as a whole is suffering from the inevitable and progressive increase in specialization. How do we propose to deal with this situation ?

I claim no originality in raising this general question and offer no solution at this stage. It is evident that underlying the numerous symposia, conferences, joint-meetings and so on, that from time to time have been convened, the same or a not dissimilar point of view has obtained ; but a more definite policy needs to be framed, continuously pursued and kept to the fore in our biological deliberations. The question of *how* this is to be done is for botanists collectively to decide. The time for doing so is at hand if a great opportunity is not to pass unheeded.

In conclusion, I wish to express my gratitude to colleagues for suggestions and much helpful criticism ; but for the opinions expressed responsibility lies wholly with myself.

SCIENCE AND INDUSTRY*

By J. G. BENNETT

Director, British Coal Utilisation Research Association

CURRENT discussions as to the part which science should play in industry are often vitiated by misconceptions as to what science and the scientific activity really are. Science is not the mere use of scientific apparatus to ascertain facts, nor the use of scientific jargon to describe them. Again, we should not use the term science to include the testing of materials and the control of technical processes as practised in modern industry. All this should be regarded as part of engineering and production technique, which only incidentally requires particular kinds of apparatus and men with a particular training. Science is not primarily a matter of technique but a *specific activity of the human mind*.

The scientific activity is as definite in its character as, for example, the artistic activity or the organizing activity, and in its highest form is as rare as either.

The basic scientific processes are observation, experiment and hypothesis formation. Hypothesis formation consists in applying to observations of natural phenomena an act of creative thought, which discovers in them a meaning which they previously did not possess. This new meaning then suggests new lines of thought and new lines of observation and experiment. The essential feature is that the new hypothesis is more than an orderly presentation of the data. It is a new view of the working of Nature, which is important as much because it is new as because it is valid.

The validity of a hypothesis is a purely relative conception, for we can never know the last word about Nature, and the whole progress of science con-

* Substance of an address at the inaugural session of the North-Eastern Section of the Institute of Fuel, Newcastle-upon-Tyne, delivered on October 18.

sists in discarding an old hypothesis in favour of a new one which is more fruitful at the particular stage which the science in question has reached. A hypothesis can be termed 'valid' in so far as it fits satisfactorily a body of observed facts and enables new facts to be predicted which can afterwards be verified by experiment and observation. In other words, the hypothesis is the actual vehicle by which scientific thought is carried forward.

The essence of the scientific method is this combination of observation and experiment with the formation of hypothesis. Science is *not* the working to some predetermined plan or schedule to find an answer to a specific question. In this lies the essential distinction between science and engineering. Any industrial process or industrial development, unless it be wild speculation, must set before itself a clearly defined aim, and the industrialist must calculate in advance the material resources which he can bring to bear and the resistance which he will have to overcome. He must have an assurance of success within what is called 'a fair commercial risk'. It is upon the engineer that the industrialist relies to provide him with the technical means for carrying the project into effect. There is an element of uncertainty in every enterprise, and the task of the engineer is to reduce that element to a minimum. However bold the project may be, he must take all possible steps to ensure that the aim specified in advance is realized within a specified time, and at a specified cost.

None of these things is possible for science. Science is continually reaching out into the unknown. It cannot calculate in advance either the results which it hopes to obtain or the time which they will take to get or their cost. Any attempt to force scientific endeavour into predetermined rigid channels destroys its very essence. The result may be useful, but it is in the highest degree improbable that it will be the creation of anything new.

The whole significance of the relations between science and industry lies in this—that it is science alone which can produce new knowledge differing not merely in precision and extent, but also in *kind*, in actual quality, from that which existed before. The industrial history of the past two hundred years shows clearly where the impact of science has been truly effective. The electrical industry owes its development to the scientific work, that is the combination of experiment and hypothesis formation, of men like Faraday, Clerk Maxwell, Hertz and Röntgen. The fine chemical industry is founded on the experiments and hypothesis formation of men like Perkin, Kekulé, Fischer and Baeyer.

It is only in the present century that the attempt has been made to bring the scientific method, properly so-called, into industry as an effective part of its operations, although it should be noted that in the highly productive period between 1750 and 1900, scientific men were themselves very much interested in the practical significance of their discoveries. The new idea that there are two kinds of scientific workers to be called respectively 'fundamental' and 'applied', one concerned with the advance of knowledge for its own sake and the other with the material results of scientific work, is an artificial one and is highly misleading. The collected scientific papers of men like Benjamin Franklin, Humphry Davy, Liebig, Pasteur and Kelvin make it clear that they regarded the pursuit of knowledge and the application of knowledge as an indivisible whole. There is no suggestion of a conflict of motive in their scientific work. It has been a retrograde step in the present century to try to distinguish between fundamental and applied science or between 'pure' and 'commercial' men of science. There is only one kind of science, and that is *the observation of natural processes, the devising and conduct of experiments and the formation of hypotheses to account for the results.*

The question is sometimes asked whether there is a valid distinction between an engineer and a scientific worker. There is certainly such a distinction, for the engineer is not concerned with hypotheses, and his attitude to observation and experiment should be essentially different from that of the scientific man. The engineer's object is to make things work. He is not interested in new knowledge for its own sake. He dislikes accidents and tries to avoid being confronted with unexpected occurrences. The man of science is above all interested in the unexpected. He does not in the least mind making mistakes, providing that they teach him something. His most fertile raw material is the experiment that goes wrong, giving a result that cannot be explained in terms of existing knowledge or theories.

A survey of the elements in industrial progress would not be complete without reference to the *inventor*. The inventor belongs to a different category and must not be confused either with the scientific man or with the engineer, though of course it is possible to have inventors who by training are scientific men and inventors who are engineers. The true inventor is not really concerned with knowing *why*, like the scientific man, or knowing *how*, like the engineer. His urge is to create; he is interested in novelty for its own sake, and he prefers to do something in a new way even if at first sight it may not offer obvious advantages over the old ways.

It is particularly important to recognize the difference in the contributions which the man of science and the inventor have to make to the progress of industry, because, on the whole, in the future, the importance of the man of science is likely to grow and that of the inventor to diminish. This is because the inventor shows to the greatest advantage where technique is primitive, and the man of science becomes more and more effective as technique is advanced.

One other misconception that needs to be removed is that 'scientific' means 'meticulously accurate'. So far from the man of science being interested in exact measurement for its own sake, he would be the first to agree that mere measurement has little value in itself. Very often rough exploratory experiments, made to find out whether things will happen in the accepted way or not, have led to far more important discoveries than a host of accurate measurements made with costly apparatus and no creative idea behind them.

To sum up, it may be stated that the true opposite of science is *empiricism*. Empiricism consists in using the results of observation and experience without attempting to understand their meaning, that is, without forming a hypothesis. A very great deal of what goes by the name of scientific research, particularly in industry, is empirical, and is therefore unlikely to lead to new knowledge and new points of view. The empirical attitude is right and indeed indispensable in the engineer, but it is wrong in the scientific worker.

With this outline of the true nature of science, attention can be turned to the question of the position of science in industry. There are essentially three

partners in the enterprise of bringing a scientific discovery into general use. The first is the scientific worker who discovers the *new* piece of knowledge. The second is the engineer who combines that new knowledge with existing knowledge and experience to make something which will *work* on whatever scale may be required. Third, there is the industrialist whose judgment, powers of organization and management provide the engineer with the conditions required for his activity and convert the enterprise into what is known as *a going concern*.

These three partners do not speak the same language, and are liable to misunderstand one another in a very dangerous way in their attempts at intercourse through the medium of garbled translation. A scientific worker is apt to view with impatience the insistence of the industrialist upon the fulfilment of certain practical conditions before he is ready to bring his resources and organizing capacity to bear on a new discovery. On the other hand, the scientific man's attempt to interpret in concrete terms of commercial production what is really a new way of thinking about the world, is apt to convey either an impression of undue optimism or else of mere vagueness and muddle. Is it then the engineer who can serve as the intermediary between the man of science and the industrialist ? This would be a mistaken solution, for engineers are essentially conservative. They rightly prefer to rely on established practice or the minimum departure from it to meet the requirements of a given problem. It is the engineer's duty so far as possible to minimize risks.

The position becomes clearer when the characteristics of a successful industrialist are examined. He must have imagination and be receptive to new ideas. Above all, he must have a capacity for seeing the possibilities inherent in a situation earlier and more clearly than his competitors. He must have judgment to weigh successfully the favourable and the adverse factors in an enterprise. In other words, he must be able to see not only the possibilities but also the difficulties in a realistic way.

Now these are just the qualities which should be applied to a new piece of scientific knowledge if it is to be used rapidly to the greatest effect. It is by combining the outlook of the man of science with that of the industrialist that the significance of a new discovery can best be gauged. It is only rarely that a scientific man has also a natural capacity for industrial insight and judgment, and is able himself to direct his work into productive channels. The conclusion is therefore reached that the man of science and industrialist are natural allies. They have more in common than either usually can appreciate, but it is difficult for them to work together not merely because they speak different languages but also because they deal with different kinds of facts. Yet any industry, where the industrialists and scientific men really come together, will make technical progress of a kind that has not been seen since the beginning of the industrial epoch. This cannot be achieved by attempts on the part of the scientific workers to popularize their ideas, or by industrialists seeking to gain a smattering of science. It can only come if scientific men take the trouble to study and understand the kinds of facts which form the subject-matter of industrial activity, and also if the industrialists try to understand what is meant by the formulation of a new scientific hypothesis. Neither of these two things is so difficult as might be thought. The mistake that is made at present when the man of science tries to explain his work to industry, is that he tends to describe experiments and observations, to give numerical examples, or attempts to forecast some practical application. He does not try to convey the *meaning* of his work, the new point of view which he has reached. This is what really matters in the scientific method, for this is the true creative work which the man of science alone can do.

THE ARGENTINE EARTHQUAKE

By ERNEST TILLOTSON

ON January 15 at about 8.51 p.m. (local time) one of the strongest earthquakes of Argentine history occurred in the Andean Province of San Juan. The epicentre of the earthquake was near the chief town in the province, San Juan, which is situated at latitude 31° 38′ S., longitude 68° 38′ W., and at this place as well as in the nearby villages there was great destruction of property and loss of life. In addition to San Juan Province, the Provinces of Cordoba, Mendoza and Larioja were affected, the latter seriously. The shock was felt throughout most of the remainder of the Argentine, and also in Chile and in Uruguay. It was recorded on seismographs at many observatories throughout the world, including some in Great Britain. At La Plata it was recorded very strongly, and at Buenos Aires the recording suddenly ceased nearly as soon as it began owing to the violent, large amplitude earth waves being too great for the pendulum, which became unhinged. The recording needles of the instrument were also broken.

In San Juan, a city with a population of about eighty thousand people, about two thirds of the buildings immediately collapsed, and others were damaged in varying degrees. Among the large buildings thus affected were the cathedral, numerous churches, Government House, municipal buildings, the railway station and the post office. Fissures and fault cracks appeared in the streets. Electric cables were broken, gas mains were shattered, water pipes were burst open, and telephone communication within the city and to the outside world ceased. Roads, especially the narrow ones, were blocked with the debris of crashed buildings, and rail traffic was stopped by fissures, fallen debris and twisted rails. In the city fires raged, having been started by the shaking of hot coals from the fireplaces, by gas escapes and by electric short circuits. Even if the fire brigades could have got to them, there would have been no water supply, and so they burned themselves out unchecked. Unfortunately, at the time many people were in cafés, cinemas and restaurants and were trapped in the buildings and narrow streets. The death roll is undoubtedly high, and three thousand bodies have so far been found and burned. More than another three thousand are injured, and when the casualties in the surrounding villages are counted the death-roll may be as high as five thousand. Fortunately rail communication with Mendoza was quickly resumed, and radio communication with the city was found possible. Drinking water was sent from Mendoza, one hundred miles away. Many of the people are now living in tents and relief work is in progress. San Juan is to be completely evacuated and cleared, and when it is rebuilt it will be spacious and the buildings will be of earthquake-proof design. The evacuation would

appear inevitable as aftershocks, including a very violent one some thirty-six hours after the first earthquake, caused buildings previously damaged to collapse, and damaged most of the remaining ones.

In Buenos Aires in the eastern Argentine the original earthquake was sufficiently pronounced to sway street lamps. The shock was also distinctly noticeable in the upper stories of sky-scrapers. The last strong earthquake which affected San Juan and destroyed some property occurred on October 27, 1894. On that occasion La Rioja was also affected, though the shock was not so severe as the present one. The Argentine is definitely a country where earthquakes are liable to occur from time to time, though it is not so greatly affected as its neighbour Chile. It is that part of the Argentine nearest to the Andes Mountain Chain which is most affected and not so much the eastern plains. The Andes form part of the great circum-Pacific belt of instability, round which more than half of the world's great earthquakes occur. Although earthquakes of destructive violence have happened from time to time in the twentieth century in the Argentine, they have usually been centred away from densely populated areas and towns. In the nineteenth century there were several outstandingly destructive shocks. On April 9, 1849, San Luis was destroyed. On March 20, 1861, Mendoza experienced widespread destruction, and on October 22, 1871, Jujuy and Oran suffered this same fate, to name a few outstanding examples.

NEWS and VIEWS

Sir Richard Gregory, Bart., F.R.S.

JANUARY 29 marks the eightieth birthday of Sir Richard Gregory, president of the British Association and formerly editor of NATURE. To many who have known him, this may come as a surprise, for his energy and alertness seem unabated with the passage of years. Upon his retirement from the editorship of NATURE at the end of 1938, Sir Richard gave scientific men a message which in some ways may be regarded as his own philosophy of life (see NATURE, January 7, 1939, p. 1). In it he shows his profound belief in the significance for the future of mankind of scientific progress and its application to human affairs. His labours to this end were fittingly acknowledged by his election in 1933 to the Royal Society, under the special rule which permits election to the fellowship for "conspicuous service to the cause of science".

But Sir Richard did not retire from public life when he relinquished his editorial post at the age of seventy-five; his new leisure was quickly occupied with other interests. During the forty-five years of his association with NATURE, he had always taken a prominent part in the work of the British Association, and in particular of Section L (Education), which he served in many capacities, becoming president in 1922. Finally, at the ill-fated meeting at Dundee in 1939, which had to be abandoned through the outbreak of war, he was elected president of the British Association for 1940 (see NATURE, September 9, 1939, p. 472), and has, of course, remained in that office since. Due largely to his initiative, the Association, through the new Division for the Social and International Relations of Science, has, in spite of war-time conditions, managed to hold meetings of limited scope in Reading, Manchester, and London. Sir Richard Gregory has made many friends on his visits to South Africa (with the British Association), to India and to the United States, who will feel a particular interest as they join with other scientific men in congratulating him upon his past achievements and sending him their good wishes for the future.

Colonial Products Research Council: Report

THE first interim report of the Colonial Products Research Council states that the procedure adopted, which was modelled on and adapted from that of the Department of Scientific and Industrial Research, the Medical Research Council and the Agricultural Research Council, is to make the fullest possible use of existing research facilities in universities and other institutions, delegating to them the investigation of specific problems on terms mutually arranged. Researches already planned or initiated in this way include investigations on sucrose and sucrose derivatives under Prof. W. N. Haworth at the University of Birmingham; on eugenol and *iso*eugenol under Prof. G. R. Clemo at the University of Durham; on lime oil, lime juice and citrus under Prof. I. M. Heilbron at the Imperial College of Science and Technology, London; on fixed oils and fats under Prof. T. P. Hilditch at the University of Liverpool and Dr. Ida Smedley-MacLean at the Lister Institute; on caffeine and theobromine under Prof. A. R. Todd at the University of Manchester; on petroleum products under Sir Robert Robinson at the Dyson Perrins Laboratory, Oxford; and on the production of ergosterol at the Chemical Research Laboratory under Dr. A. C. Thaysen. The Council is also engaged in reviewing the field of research into vegetable drugs. The Director of Research has been accommodated at the Imperial Institute by the courtesy of Sir Harry Lindsay. While the function of the Council is to organize and sponsor fundamental and applied researches on Colonial commodities, with the primary object of finding new uses for them, the Institute will continue its chemical investigations of Empire raw materials in accordance with its statutory obligations and will furnish information to producers and potential customers on sources of supply, markets, the preparation of commodities for commercial and industrial use, and the economic possibilities for any given commodity, etc.

The Education Question: a Biological Approach

THE inaugural address at the University of Leeds School of Medicine delivered last autumn was by Sir John Graham Kerr, who announced as his subject "Medicine and Education". To what extent the substance of the address answered the expectations of the audience is perhaps doubtful, but there is no doubt whatever that it answered to one of the needs of the hour. Sir John pointed out that, among primitive peoples, a boy becomes a highly trained observer by eye and ear, he acquires the ability to interpret rapidly and correctly what he observes and he learns to keep his wits constantly alert. As boyhood passes into adolescence, he accompanies his elders on their expeditions, and his education continues as before. That the education of to-day has departed so widely from its original

type is, added Sir John, due, paradoxically, to one of the most beneficent events in the history of our civilization—the invention of the printed book, which brought with it the possibility of mass education. An inevitable result of the domination of education by the printed book was the reduction to a position of relative unimportance of that training in observation, judgment and mental alertness which formed so important a part of education in the earlier phases of communal evolution. In the child's pre-school life, we still have that kind of training, as also in later adult life of vocational employment. But in the intervening period of school life, the boy becomes in the main an absorber of information obtained from the printed page. The remedy lies not in further overloading the school curriculum, but in correcting some of the existing wastage. As to girls' education, Sir John, believing it to be a question for the women of the country, declined to commit himself, except to say that the education of a girl should be permeated with the realization that the highest ideal of her sex is that of home and family.

Higher Education in the Caribbean

THE Commission on Higher Education in the Colonies (see NATURE, August 21, 1943, p. 211) has appointed a committee of its members, and co-opted representatives from the West Indies, with the following terms of reference: "To review existing facilities for higher education in the British colonies in the Caribbean and to make recommendations regarding future university development for these colonies." The committee is constituted as follows: Sir James Irvine (chairman), vice-chancellor of the University of St. Andrews; Prof. A. M. Carr-Saunders, director of the London School of Economics and Political Science; Miss Margery Perham, reader in Colonial administration at the University of Oxford; Dr. R. E. Priestley, vice-chancellor of the University of Birmingham; Mr. P. Sherlock, secretary of the Institute of Jamaica; and Mr. H. Springer, member of the House of Assembly, Barbados; with Mr. T. R. Rowell, assistant educational adviser at the Colonial Office (secretary). The committee will spend some three months visiting Jamaica, Trinidad, Barbados and British Guiana. Mr. W. D. Inniss, lately assistant master at Queen's Royal College, Trinidad, will serve on the committee while it is in Trinidad, and Mr. J. A. Luckhoo, member of the Executive and Legislative Councils, British Guiana, while it is in that colony.

An Idealist View of Special Publications

IN a paper "Streamlining Production and Distribution of Current Periodical Articles" (*Special Libraries*, 34, No. 6, July–August 1943), Zeliaette Troy, librarian of the Boyce Thompson Institute for Plant Research, after directing attention to the difficulties which the present system of publication offers to individuals as well as to libraries, and to the drawbacks of inter-library loans, film copies and photostat copies, suggests a scheme for minimizing the mechanics of publication and distribution. Under this scheme, an author would complete his article and send it to the usual editors, by whom, on approval, it would be sent to a central printing office. There the manuscript and abstract would be stamped with the date of receipt, and the authorizing organization indicated. When the article and abstract are in printable form, they would receive a common chronological number, followed by a classification number, after which the cost accountant would put a price on the article and on the abstract in accordance with the number of copies to be printed, and both items would go to the printing establishment.

The printers would thus supply a stream of scientific articles uniform in size, with the author, title, name of the organization sponsoring and paying for it, the date of receipt, the master number and the classification number or numbers. They would also supply a periodical index and abstract journal issued both in its entirety and by subject sections. Members of a subscribing organization would receive one copy each of the publications authorized by it. Individuals or libraries subscribing for all articles in certain classifications would be similarly supplied. The index-abstract journal would have an annual paid subscription charge both for the complete issue and its sections.

The advantages of the proposed system to the individual, in the absence of delays in publication and in being sure of seeing all articles on the subjects falling within the classifications for which he subscribes, in the relief from the burden of proof-reading and the distribution of proofs are clearly indicated, and the failure of the individual to distinguish between his working tools and his 'browsing' literature is emphasized: the latter might well be left to his library, and only those articles of fundamental and immediate importance to him taken into his private collection. Libraries would have the further advantages of being relieved of inter-library loans and expensive and inadequate reproductions. Binding problems would be simplified and some binding could be eliminated.

Geological Society: Medal Awards

THE Council of the Geological Society announces the following awards: Wollaston Medal to Prof. V. M. Goldschmidt, professor of geology, Frederiks University and Museum, Oslo, for his outstanding contributions to Norwegian petrology, and his fundamental researches into the structure of crystals and the distribution of the chemical elements in the earth; Murchison Medal to Prof. V. C. Illing, of the Imperial College of Science and Technology, for his talented contribution to oil geology and Palæozoic stratigraphy; Lyell Medal to Dr. N. R. Junner, of the Geological Survey of the Gold Coast and Sierra Leone, for his contributions to the stratigraphy of the Pre-Cambrian and his discoveries of valuable minerals associated therewith; Wollaston Fund to Mr. A. G. Brighton, curator of the Sedgwick Museum, Cambridge, for his services to palæontology and his researches on the echinoderms; Murchison Fund to Mr. G. M. Stockley, of the Geological Survey, Tanganyika Territory, for his work on the stratigraphy, palæontology and mineral resources of East Africa; one moiety of the Lyell Fund to Dr. S. Buchan of the Geological Survey of Great Britain, for his work on underground water resources of the London area; another moiety of the Lyell Fund to Mr. E. W. J. Moore, of Haslingden, for his researches on carboniferous goniatites.

Presidency of the American Chemical Society

PROF. C. S. MARVEL, professor of organic chemistry in the University of Illinois, has been elected president of the American Chemical Society for 1945. Prof. Marvel will take office as president-elect on January 1,

1944, when Dr. Thomas Midgley, jun., vice-president of Ethyl Corporation, and known for his discovery of tetraethyl lead, becomes president, succeeding Dr. Per K. Frolich, director of the Chemical Division, Esso Laboratories, Standard Oil Development Company, Elizabeth, New Jersey. Dr. Marvel was recently awarded the 1944 William H. Nichols Medal of the New York Section of the American Chemical Society. He has made outstanding contributions to research on the structure of vinyl polymers, used as synthetic plastics, particularly in the production of transparent aircraft parts, as rubber substitutes, and as thickening and blending agents in the chemical manufacturing industry. He has also made important researches on the structure of polymers of sulphur dioxide and olefines, and has developed practical methods for preparing amino-acids.

Wind and Bird-Migration

DR. NORMAN H. JOY (*Field*, Dec. 11, 1943) has published a short account of observations on bird-migration maintained almost continuously for four years at Dungeness, on the coast of Kent. This is useful work, of a kind not often undertaken so intensively. He has, in particular, noted the conditions of departure across the English Channel in autumn. As only selected observations are given, it is difficult to make a critical assessment of the conclusion that birds of certain species, for example, swallows, leave only when there is a contrary wind. The frequency with which birds are seen migrating against the wind has often been remarked. To some extent the impression may be exaggerated—birds flying across the wind (as Dr. Joy points out) have to head partially into it to correct their drift; and birds flying against the wind, at reduced speed in relation to the ground, remain longer under notice. In any event, it is open to question whether the relation between wind and a migratory movement is one of cause and effect, or whether they have a common origin in the general meteorological situation. Dr. Joy's suggestion that birds find a head wind advantageous because it gives them more lift is untenable: once it is airborne, a bird can derive no lift from the body of air within which it moves (assuming, for simplicity, that the current is horizontal and of uniform strength), except as a result of its own air speed.

Poisonous Reptiles of the World

THE Smithsonian Institution "War Background Studies", No. 10 is on the poisonous reptiles of the world, by Doris M. Cochran (Smithsonian Inst., 1943). It contains brief accounts of all the principal poisonous reptiles arranged in geographical groups, namely, the United States, Latin America, Europe and northern Asia, India and Malaya, Africa and Australia, New Guinea and the South Pacific Islands. The brochure is illustrated with seventeen plates, the first of which is coloured and most of which contain two species. There is also a small selected bibliography and an appendix dealing with first aid treatment, the preparation of antivenin and directions to collectors. From it medical officers should be able to identify any of the ordinary poisonous reptiles with which they are likely to be concerned even without previous knowledge of the group. It is obvious also that it will be useful to others than to those for whom it is particularly written.

Fishes from Philippine Seas

HENRY W. FOWLER has described many new fishes in his recent paper "Contributions to the Biology of the Philippine Archipelago and Adjacent Regions. Descriptions and Figures of New Fishes obtained in the Philippine Seas and Adjacent Waters by the United States Bureau of Fisheries Steamer *Albatross*" (U.S. National Museum, Bull. 100, **14**, part 2. Smithsonian Institution, 1943). These belong to several families and form an appendix to the detailed reports on these groups of *Albatross* fishes. There are ten new genera, one new sub-genus, one new sub-family and twenty-two new species in this paper. Many of these fishes are of striking form, notably *Calliurichthys lineathorax* n.sp., with its enormously long caudal fin as long as all the rest of the fish. All the illustrations are excellent.

The Night Sky in February

FULL moon occurs on Feb. 9d. 05h. 29m. U.T., and new moon on Feb. 24d. 01h. 59m. The following conjunctions with the moon take place: Feb. 3d. 06h., Mars 7° N.; Feb. 4d. 07h., Saturn 3° N.; Feb. 9d. 11h., Jupiter 0·4° S.; Feb. 21d. 20h., Venus 1° S.; Feb. 22d. 20h., Mercury 1° S. The following occultations of stars brighter than magnitude 6 take place: Feb. 4d. 22h. 58·6m., 57 Ori. (*D*); Feb. 5d. 03h. 23·6m., 64 Ori. (*D*); Feb. 7d. 18h. 36·7m., d^1 Canc. (*D*); Feb. 7d. 23h. 43·0m., θ Canc. (*D*); Feb. 17d. 06h. 01·1m., η Lib. (*R*). The times refer to Greenwich and *D* and *R* refer to disappearance and reappearance respectively. Mercury rises at 6h. 28m. at the beginning of the month and at 6h. 44m. at the end of the month, and is too close to the sun to be favourably seen. Venus rises a little before 6h. throughout the month and is a conspicuous object in the morning hours. Mars can be seen through a good portion of the night, setting at 3h. 57m., 3h. 26m., and 2h. 56m. at the beginning, middle and end of the month. Jupiter is in opposition on Feb. 11 and can be seen throughout the night, setting at 8h. 21m. and 6h. 20m. at the beginning and end of the month. Saturn is a little east of Mars and sets about 15 minutes later than Mars in the middle of the month. At the beginning and end of the month Saturn sets at 4h. 35m. and 2h. 42m. The planet is stationary on Feb. 20.

Announcements

WE regret to announce that Dr. W. W. C. Topley, F.R.S., secretary since 1941 of the Agricultural Research Council, and formerly professor of the division of bacteriology and immunology in the University of London, died on January 21, aged fifty-seven.

THE Council of the Royal Aeronautical Society has elected Group Captain F. Whittle a fellow of the Society; such an election is a special distinction in recognition of work of great importance in aeronautics.

MR. ATTLEE, Lord President of the Council, has announced that the Government has appointed the following committee to consider and make recommendations as to the development of television after the War: Lord Hankey (chairman); Sir Noel Ashbridge and Mr. Robert Foot, B.B.C.; Sir Raymond Birchall and Sir Stanley Angwin, General Post Office; Mr. Harvey, Treasury; Sir Edward Appleton, Department of Scientific and Industrial Research; and Prof. J. D. Cockcroft, Ministry of Supply.

LETTERS TO THE EDITORS

Fluorescence as an Aid to Physiology

THE great value of fluorescence as a guide to physiological activities was first brought home to me in 1925, when I observed that cod-liver oil which had been exposed to sunlight had lost its fluorescence. Following up this simple observation, I found that the loss of fluorescence was accompanied by the loss of vitamin A[1]. The value of fluorescence in the search for pure chemical carcinogens was proved by Kennaway and Hieger[2], who used the fluorescence of carcinogenic fractions of tar as a guide, which eventually led to the identification of benzpyrene, though the first pure chemical carcinogen identified by them was 1 : 2 : 5 : 6-dibenzanthracene, which they suspected of being carcinogenic on the strength of its fluorescence and absorption spectra.

During the past eighteen years, I have repeatedly made use of fluorescence in a variety of experiments the primary purpose of which was related to cancer, but in the course of such work I have repeatedly noted observations of physiological interest, some of which have been described in journals devoted to cancer research and thus not likely to excite interest among those concerned mainly in experimental physiology. It seems possible that some of these observations might be of interest apart from their bearing on cancer, and, in this hope, I should like to place them on record.

(1) As a method of demonstrating the great speed at which substances can travel in the blood stream, I know of nothing so striking as a fluoroscopic examination of blood collected drop by drop from one ear of a rabbit during the period of injection into a vein of the opposite ear of a colloidal suspension of benzpyrene or anthracene, every particle of which is brilliantly fluorescent. In this way, it is possible to demonstrate that the maximum speed of circulation is much greater than one would estimate from experiments in which dyestuffs are injected, as the sensitivity of the fluorescent method is enormously greater than that of colorimetric methods. Many fluorescent substances can readily be detected in dilutions of more than one in a million, and, in the case of colloidal suspensions, in far higher dilution.

(2) The rapidity with which such fluorescent particles disappear from the circulating blood (within fifteen minutes) led to the observation of the mechanism of elimination of hydrocarbons, which has been published in detail elsewhere[3], and illustrated, incidentally, a beautiful method of visualizing part of the mechanism of excretion by the liver. This is so striking and so easily demonstrated that one would think it must be of interest to those who teach students about the physiology of the liver. The change from the colloidal state to true solution, in the liver, and the metabolism to the hydroxy-compound can also be visualized clearly in the case of benzpyrene, owing to the different coloured fluorescence seen in different stages of the process. The subsequent excretion in the bile demonstrates the rate of secretion and excretion of the fluid, and can also be used to show peristaltic waves passing along the intestine and the rate of movement of its fluid contents. Moreover, it can be shown that in the case of chicks *in ovo* the gall-bladder does not contract; so the bile with which it is filled remains non-fluorescent after intravenous injection of fluorescent substances, while the hepatic ducts and intestine stand out in striking contrast, by reason of their content of fluorescent bile. In the newly hatched chick, however, as soon as it begins to peck food or even eggshell, the gall-bladder contracts and rapidly fills with fluorescent bile, thus demonstrating that contraction of the gall-bladder is related to the presence of food in the alimentary canal. Some of these observations have been published[4].

(3) Recently, I have observed a striking and peculiar appearance in the cæcum of a mouse following a fluorescent meal. Fluorescence of the organ in this animal showed a sharp line of demarcation dividing it axially into fluorescent and non-fluorescent parts, the fluorescence being limited to the concave half of the organ. Although I have repeated this experiment a few times, I have not again killed an animal at the precise time at which this phenomenon could be observed, suggesting that it is only of very temporary duration, but possibly throwing light on the method of action of this organ.

(4) As a last example, I should like to cite what, for want of a better name, I have termed 'loop-way' excretion by the liver of substances that are finally excreted by the kidney. This can be beautifully illustrated by injecting mice intravenously with 1 per cent fluorescein solution, and killing them at intervals up to one hour or more after injection. It will be seen in such experiments that the liver and kidney simultaneously excrete the dye, so that it is voided in the urine at the same time that it is being excreted into the bile and so into the intestine. As this substance is readily diffusible, it is rapidly reabsorbed from the intestine, while renal excretion continues to lower the blood level of the substance. In this way, finally, it is all excreted in the urine. Thus, if one limited the experiment to observations on the amount injected and the amount excreted in the urine, no evidence would be obtained of the important loop-way action of the liver in lowering the blood level. Many other substances, including indigo carmine, used in renal efficiency tests, can be shown to follow the same route in animals with experimental biliary fistulæ.

Some of these observations have appeared, as stated above, in journals not devoted to physiological experiments; others have not been published at all. I am not primarily concerned with physiological experiments, and so cannot devote time to pursuing them as far as I could wish. It is possible that such effects are already well known to some physiologists; but I believe that this is not generally true and that it is not widely appreciated how very easy the detection of fluorescent substances in the animal body can be. The only apparatus required is a source of ultra-violet rays, screened by Wood's glass, and a dark room in which observations can be made by an observer whose eyes are adapted to the dark.

Function of Carbonic Anhydrase in Blood

CARBONIC anhydrase, which catalyses the reversible reaction

$$CO_2 + H_2O \rightleftarrows H_2CO_3,$$

is an intracellular enzyme found in high concentration within red blood corpuscles[1]. The activity of this enzyme and the kinetics of the reactions it catalyses have been studied mainly either with laked corpuscles or with hæmoglobin-free enzyme preparations. Suspensions of intact corpuscles tested by the usual colorimetric or manometric methods were found to be almost completely inactive. The activity of carbonic anhydrase within the red blood corpuscles, as well as its relationship to the chloride shift, were demonstrated spectroscopically by Keilin and Mann[2]. They used for this purpose red cells in which hæmoglobin had been oxidized to methæmoglobin; the latter acting as an indicator changing its colour and absorption spectrum with the pH of the surrounding medium. The activity of carbonic anhydrase was determined by them from the velocity of these changes in presence and in absence of sulphanilamide, which they found to be a highly specific inhibitor of this enzyme[3].

The present communication summarizes the results of experiments which demonstrate that the uptake and liberation of carbon dioxide can be catalysed by the carbonic anhydrase present within normal intact red blood corpuscles.

The experiments on the velocity of carbon dioxide uptake were carried out as follows: 20 ml. of horse blood or of a suspension of corpuscles are put in a 350 ml. flask, carefully evacuated and equilibrated with pure nitrogen or pure oxygen. 10 ml. of this blood is introduced through one of the apertures into a 250 ml. Woolf bottle filled with a gas mixture containing 5 per cent carbon dioxide in nitrogen or in oxygen. The bottle is fixed to a stationary shaking apparatus and its second aperture is connected by means of a three-way tap to the manometer. When the temperature is equilibrated, the taps are closed and the bottle is violently shaken and the manometer is read every 15 seconds. The same procedure was adopted for the study of the liberation of carbon dioxide, the only difference being that the blood was first equilibrated with the gas mixture containing 5 per cent carbon dioxide and then transferred to the Woolf bottle containing pure nitrogen or pure oxygen.

The results of these experiments, which are shown in Fig. 1 (*A* and *B*), can be summarized as follows: (1) The velocities of either the uptake or the liberation of carbon dioxide are markedly decreased by the addition of a small amount of sulphanilamide, but are not affected by sulphapyridine, which confirms the previous observations by Mann and Keilin[3] as to the effects of these drugs on carbonic anhydrase. (2) Although sulphanilamide decreases the velocities of these reactions, it has no effect on the equilibrium point, which is ultimately reached and which depends only on the total buffering capacity of the sample tested. In fact, by extrapolation Curve 4 will meet Curve 1. (3) Sulphanilamide will thus differentiate the buffering capacity of corpuscles from their catalytic activity, both of which influence the velocities of carbon dioxide uptake and liberation. (4) The slowness of carbon dioxide uptake or liberation by serum alone after the first minute of the reaction is partly due to its low buffering capacity. (5) In all these experiments the velocity of carbon dioxide liberation was lower than that of uptake. This may be due to the state of oxygenation of hæmoglobin. However, further experiments are

(1) 50 per cent blood corpuscles; (2) 50 per cent blood corpuscles + 0·4 ml. conc. sol. of carbonic anhydrase; (2*A*) 50 per cent blood corpuscles + 0·1 ml. conc. sol. of carbonic anhydrase; (3) the serum-saline mixture alone; (4) the serum-saline mixture + 0·4 ml. concentrated sol. of carbonic anhydrase.

required for an adequate explanation of this phenomenon.

The relationship between the activity of carbonic anhydrase and the chloride shift was postulated by Roughton[4] and demonstrated by Booth[5] and by Keilin and Mann[2]. This was confirmed in the course of the present investigation. As shown in Fig. 2, the activity of the red blood corpuscles washed in isotonic phosphate solution and suspended in 6 per cent glucose solution is much lower than the activity of these corpuscles suspended in glucose solution which was diluted with an equal volume of 0·9 per cent sodium chloride. The activity of corpuscles in absence of sodium chloride was not, however, completely abolished, since it is still higher than that of the same suspension poisoned with sulphanilamide.

The fact that on hæmolysis of the red blood corpuscles, which may occur under certain pathological conditions, carbonic anhydrase is liberated into the plasma suggested the study of the influence of the extra-corpuscular enzyme on the catalytic activity of corpuscles. For this purpose the activity of the suspension of corpuscles in diluted serum or 0·9 per cent sodium chloride was tested with and without the addition of free carbonic anhydrase. The results of these experiments, summarized in Fig. 3, show that the catalytic activity of corpuscles in the liberation of carbon dioxide is distinctly inhibited by the presence of an extra-corpuscular enzyme, and that the degree of this inhibition is proportional to the concentration of enzyme. On the other hand, the carbon dioxide uptake does not seem to be affected by the presence of an extra-corpuscular carbonic anhydrase.

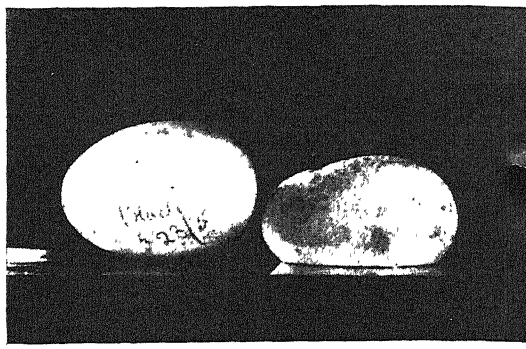
Carbonic Anhydrase, Sulphonamides and Shell Formation in the Domestic Fowl

Meldrum and Roughton[1] were the first to advance the hypothesis that carbonic anhydrase might play a part in egg-shell formation by influencing the rate of formation of the anion of calcium carbonate by catalysis of the reaction $CO_2 + H_2O = H_2CO_3$. Following up this suggestion, Common[2] examined the tissues of the hen's oviduct for their carbonic anhydrase activity, and concluded "that the carbonic anhydrase activity of the uterine epithelium is higher than that of the remaining oviducal tissues, and that this activity may play a part in shell secretion". On the other hand, it has been demonstrated by Keilin and Mann[3] that compounds of the $R SO_2NH_2$ type (where R is a benzene, naphthalene or pyridine ring) specifically inhibit carbonic anhydrase in very small concentrations. This property, however, is absent in all such compounds in which the sulphonamide group is substituted, as it is, for example, in sulphapyridine or sulphathiazole.

With these findings in mind, we administered representative compounds of the unsubstituted and substituted $R SO_2NH_2$ type to laying hens, in order to investigate their effect on shell secretion. It was



first necessary to ascertain an appropriate dose, which would not produce any of the undesirable symptoms of sulphanilamide poisoning such as cyanosis, dyspnœa and muscular weakness, and would nevertheless inhibit carbonic anhydrase to a sufficient extent. Birds were given sulphanilamide in gelatine capsules *per os* and the concentration of the drug in the blood was estimated. The results agreed well with those of Litchfield, jun.[4], with regard to the maximum concentration obtainable with different doses, although blood-levels varied according to the rate of absorption by different birds (Table 1).

TABLE 1. BLOOD CONCENTRATION OF (FREE) SULPHANILAMIDE IN MGM./CENT. (DOSE, 0·1 GM./KGM.)

Birds	6 hr.	24 hr.
1	2·46	4·92
2	5·48	2·90

Finally, a single dose varying from 0·1 to 0·2 gm./kgm. was adopted and administered to nine laying hens (five Rhode Island Reds and four Light Sussex). In every case there was a marked effect on the shells laid, varying from an entire absence of shell to a completely formed but very thin and characteristically pitted shell. The same birds were afterwards given sulphapyridine and the shells obtained were normal throughout. In the photograph are shown two eggs, laid by the same hen, the shell-less one being laid when the hen was receiving sulphanilamide and the normal one when it was being given sulphapyridine.

It should be emphasized that throughout these experiments the birds showed no ill-effects whatsoever, and their appetite and laying capacity seemed unimpaired.

The concentrations of free and acetylated sulphanilamide and sulphapyridine in the homogenized egg-contents were determined, wherever possible, using Mawson's[5] modification of Werner's method. Some of the results are given in Table 2.

TABLE 2. CONCENTRATION OF SULPHONAMIDES IN THE EGG-CONTENTS IN MGM./CENT. (i = free; ii = acetyl)

a. Sulphanilamide

Birds	Days after dosing 1		2	
	i	ii	i	ii
3	1·64	7·75	0·36	2·42
7	3·54	10·01	0·68	1·76

b. Sulphapyridine

Birds	Days after dosing 1		2		3		4	
	i	ii	i	ii	i	ii	i	ii
5	0·70	1·06	0·56	1·63	0·38	0·65	—	—
6	0·52	0·56	—	—	0·86	0·05	0·23	0·11

Birds	Days after dosing 5		6		8	
	i	ii	i	ii	i	ii
5	0·35	1·19	0·50	—	—	—
6	0·46	1·30	—	—	0·19	—

The following points emerge from these experiments: (1) Acetylation in the hen is pronounced,

which again confirms the findings of Litchfield. This does not, however, interfere with the purpose of the experiments, since acetylation takes place at the para-amino group and the total amount of active sulphonamide group remains undiminished.

(2) The inhibitory action of sulphanilamide on carbonic anhydrase is completely reversible, bearing out the observations of Keilin and Mann in their *in vitro* experiments. The effect on shell formation disappeared completely after all the sulphanilamide had been eliminated. Moreover, a graded effect on the shells was observed after the usual single dose. Thus, the shells laid on successive days showed a diminishing effect which was correlated with the decreasing concentration of sulphanilamide in the egg-contents (Table 2*a*). It was also noted that the effect on the shells laid by any one bird depended upon the time which elapsed between dosing and laying. The most marked effect was observed after a period such as could be presumed to permit of the attainment of a maximum sulphanilamide concentration in the blood during the course of shell secretion.

(3) It will be seen that the concentration of sulphapyridine in the egg-contents was always lower than that of sulphanilamide. This is a phenomenon which has been noted and discussed previously by other investigators[4,6]. In addition, sulphapyridine, unlike sulphanilamide, was excreted with great difficulty by the fowls, and was found in the eggs for so long as eight days after a single dose of 0·2 gm./kgm. These findings are probably explained by the very poor glomerular function of the fowl[4,6].

(4) It was observed that while normal egg-shells (as well as the shells from hens dosed with sulphapyridine) showed a uniform reddish-purple fluorescence in ultra-violet light, those laid by hens receiving sulphanilamide presented an uneven, blotchy fluorescence. This might be due to direct interference with porphyrin metabolism or to an irregular deposition of calcium porphyrinate, in line with the faulty shell secretion as a whole.

It therefore appears that carbonic anhydrase is essential for shell formation in the domestic fowl, for which purpose the anion of the calcium carbonate seems to be of equal importance with the cation. Thus, interference with normal anion production by way of the mechanism suggested may provide the explanation for the well-known phenomenon of pathological production of soft-shelled eggs by hens adequately supplied with calcium in a suitable form.

We are indebted to Messrs. May and Baker, Ltd., for the generous gift of sulphonamides.

Claviformin from *Aspergillus giganteus* Wehm.

THE production of a penicillin-like substance from *Aspergillus giganteus* has been described[1]. Wilkins and Harris[2] noted that this mould produced a different antibiotic when grown in a different medium, namely, dextrose 4 per cent, $NaNO_3$ 0·1 per cent, KH_2PO_4 0·1 per cent. When tap water was substituted for distilled water, production of the antibiotic was slower but the final yield greater. The mould was harvested after 4–8 weeks incubation. The active material was concentrated by adsorption on charcoal, extraction with amyl acetate and finally extraction with ethyl acetate. On concentrating and cooling this extract, crystals of active material were obtained the properties and appearance of which at once suggested that the antibiotic was identical with claviformin[3]. It had a melting point of 109° C., and no depression of the melting point was observed after mixing with a sample of claviformin.

It has recently been shown that the antibiotic patulin, isolated by Birkinshaw *et al.*[4] from culture filtrates of *Penicillium patulum*, is identical with claviformin[5,6]. The antibiotic isolated by Wiesner[7] from culture filtrates of *Aspergillus clavatus* is also identical with claviformin[6]. Thus claviformin is now known to be produced by at least four fungal species.

Use of Casein Hydrolysate in Experiments on the Nutrition of *Lactobacillus casei*

FOR some considerable time work has been going on in these laboratories on the nutritional requirements of *Lactobacillus casei*. Besides the known vitamins of the B-complex there are at least two other factors involved. These are present in the water-soluble portion of whole liver, and endeavours are being made to purify and isolate these active components.

During this work difficulty has been encountered as the active fractions become more purified, owing to the removal of other necessary nutritional requirements. It has always been appreciated in these laboratories that results using casein hydrolysate were not comparable to those given by pure amino-acid media, and prior to 1939 all work on microbiological nutrition was carried out on media of known composition. Owing to war conditions and the difficulty of obtaining adequate supplies of pure amino-acids, it has become necessary to work so far as possible with a medium based on casein hydrolysate, prepared

according to the directions of Mueller and Johnson[1]. When this is used as a source of amino-acids, it is found that besides the addition of tryptophane and cystine, the presence of leucine and *iso*leucine gives a considerable improvement in the growth and acid production obtained (cf. Happold[2] on the necessity of *iso*leucine in toxin production by *C. diphtheriæ*). An increase of 15–30 per cent in acid production has been noted. The relative insolubility of these amino-acids makes it probable that they are readily removed both from the casein hydrolysate and from the liver fractions.

On further purification, liver concentrates are obtained, for which the activity is improved by the addition of threonine. As an example it may be quoted that the activity adsorbed on, and eluted from, dialysed iron, requires threonine added to the medium. In some cases an increase in growth of up to 60 per cent has been recorded. Even with the addition of leucine, *iso*leucine and threonine, the blanks were completely negative, while with some of the more active liver concentrates, an acid production of 25 ml. 0·1 N. per 20 ml. medium has been obtained.

Consequently, when protein hydrolysates are used as the basis of media for assay work on the nutrition of *L. casei*, it is considered advisable to determine the threshold optimum for the addition of these amino-acids to the medium employed. Normally they are added to the media used in these laboratories at a level of 0·01 per cent (w./v.). (1·0 ml. of a 1 per cent solution to a litre of medium.)

We wish to thank Messrs. Roche Products, Ltd., for a grant to this department, enabling us to carry out these investigations.

Origin of the Solar System

SIR JAMES JEANS[1] returns to his original form of the tidal theory, in which the sun at the time of disruption was distended beyond the orbit of Uranus. As I was responsible for the modification that required the sun to have had approximately its present size at the time, perhaps my reasons may be restated.

There appears to be no astrophysical evidence that stars of the mass of the sun can have anything like the distension required by Jeans's theory. This might possibly be met on Lane's law by the low rate of radiation of a star at such distension, supposing it still gaseous; if there were such stars, they would probably be invisible. But I do not see how my mechanical objection can be met. We should have to provide an explanation of how the orbits of the planets could be reduced to their present sizes. They would still have to miss the sun on their first perihelion passage to avoid re-absorption; and nothing but a resisting medium seems capable of reducing the mean distances. But then we meet a dilemma. Either the medium would be revolving at nearly the same rate as the planets and would have no effect on their mean distances, or it would revolve more slowly and its density would be too small at large distances to produce any appreciable effect.

The time-scale affords a further difficulty. The age of the earth appears to be limited to 3×10^9 years at the outside, and if this datum is combined with the mass-luminosity relation, it leads directly to the result that the sun could not have been much larger than at present.

I think that the most serious difficulty of all catastrophic theories, affecting both Jeans's theory and mine, and also Lyttleton's further modification, is that the newly formed planets would need to be able to control not only the velocities of thermal agitation but also those of general expansion due to the sudden relief of pressure. I have offered some suggestions about this, but am not particularly satisfied by them. Low temperature does not appear to help.

What seems to me particularly important in the present state of the subject is to have some idea of the vapour pressures of ordinary solids at temperatures far below their boiling points. It seems clear that the majority of satellites and asteroids could not have condensed from the gaseous state under gravitation alone. But if the temperature was low enough for the saturation pressure to fall below the actual pressure, condensation would take place anyhow. If this was true in Jeans's distended star, the star would consist of dust instead of gas. In the later development of planets and satellites we have to consider densities of a resisting medium of the order of 10^{-15} gm./cm.^{3} at temperatures ranging from 100° to 400° absolute. If the density was above that of saturated vapour at the temperature considered, there would be accretion, and satellites could grow no matter how small they were; if not, their gravitational attraction would never produce more than an atmosphere. I think that the data required could be calculated, but have not been able to find them in any work that I have consulted.

HAROLD JEFFREYS.

Cambridge.

[1] NATURE, 149, 695 (1942); 152, 721 (1943).

THE theory outlined by Dr. H. Alfvén[1] appears to overlook an essential factor in the problem of astronomical evolution. At the present time the distance of the planet from the sun is determined by the fact that it possesses a certain endowment of energy and angular momentum.

If the scattered material from which Jupiter is assumed to have been evolved was initially endowed with this angular momentum, then any effect produced by electromagnetic forces must be regarded as purely temporary and is therefore irrelevant to the main issue. On the other hand, if it is suggested that the angular momentum was acquired during the process of condensation, it is necessary to describe and explain the mechanism by which the transfer of angular momentum was effected. If the angular momentum cannot be accounted for, the theory breaks down.

If it is assumed that the galaxy consisted originally of a cloud of scattered material in the form of gas, dust and small solid particles, and that the stars, planets and satellites have been evolved by a process of condensation from this material, then an adequate theory of astronomical evolution must explain three things: (1) why the angular momentum of the solar system is so much less than the angular momentum of an equal mass of the original cloud; (2) why

the angular momentum (per unit mass) of the sun, referred to the centre of the system, is so much less than that of the planets; and (3) why the angular momentum (per unit mass) of a planet, such as Jupiter, referred to the centre of the planetary system, is so much less than that of its satellites.

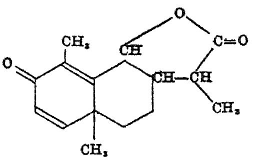
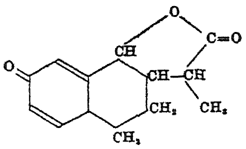
A Case of Total Asymmetric Synthesis

WE have recently announced a successful synthesis of santonin (I)[1]. We believed then that it was racemic. We have since found it to be optically active. The synthetic specimen has a rotation of $[\alpha]_D = -150$ add m.p. 171°. Sodium santoniate prepared from this sample was fractionally precipitated as the strychnine salt. This salt on decomposition gave santonin with $[\alpha]_D = -172$ identical with the rotation of natural santonin. The filtrates gave another product with identical m.p. (171°) and rotation $[\alpha]_D = -108$, which was not changed on further fractional precipitation by strychnine or quinine hydrochloride, but in no case was a dextro-rotatory product obtained. So far as we are aware, this is the first total asymmetric synthesis, apart from asymmetric synthesis carried out in the presence of polarized light, etc.

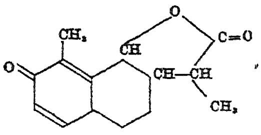
We have also prepared compounds II, III, IV and V. It has been found that asymmetric synthesis occurred only in those compounds (I, IV and V) which had an angular methyl group. The others were racemic and could be resolved into *d*- and *l*-forms through their strychnine salts.



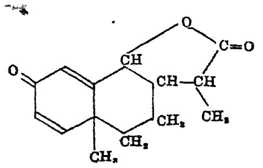
I



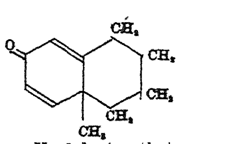
II *d*-form $[\alpha]_D = +112$
l-form $[\alpha]_D = -112$



III *d*-form $[\alpha]_D = +158 \cdot 4$
l-form $[\alpha]_D = -158 \cdot 35$

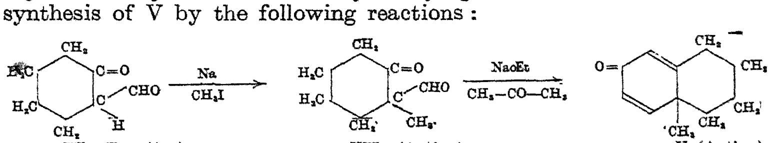


IV $[\alpha]_D$ (synthetic specimen) $= -108$



V $[\alpha]_D$ (synthetic specimen) $= -55 \cdot 65$

We have also determined the stage at which the asymmetric synthesis occurs by carrying out the synthesis of V by the following reactions:



VI (Inactive) VII (Active) V (Active)

VII is an unstable liquid and cannot be purified by distillation, and also its solid derivative could not be prepared. However, the crude substance had an optical rotation $[\alpha]_D = -26 \cdot 22$. The corresponding methylated formyl derivative used in the synthesis of santonin could not be examined for optical activity as it was highly coloured. Methylation of the formyl cyclohexanone or the corresponding derivative appears to be the stage at which the asymmetric synthesis occurs.

All rotations have been determined in chloroform solution at 28° C.

Further work is in progress.

Aerial Disinfection

THE letter from workers at the National Institute of Medical Research[1] was of interest to us, as we also find that lactic acid is an effective bactericidal aerosol, when the test organism is *C. xerosis*, emulsified in sterile saliva.

Bechhold[2] long ago advocated the use of hydroxy and carboxylic acids as germicidal aerosols. We found cinnamic and benzoic acids (both constituents of Peru balsam[3]) to be strong aerial bactericides, but acids, such as citric, fumaric, maleic, malic and phthalic tested recently proved relatively ineffective. On the other hand, maleic and phthalic anhydrides were found to be more active than their corresponding acids. In a concentration of 4 mgm./m³. and a relative humidity of about 60 per cent, maleic anhydride generally sterilized the air of our test organism within five minutes; the durability of lethal effectiveness being good, a 15-minute old mist only allowing survival of some 5 per cent of the bacteria beyond the 5-minute exposure time.

As regards the amount of germicide necessary to sterilize or nearly sterilize the air of our test organism within 5 minutes, it was found that of fifteen phenolic compounds examined, each required the vapour concentration to be of the order of 25 per cent saturation. Saturation at 20° C. was calculated from the vapour pressures deduced from the formula of Clausius and Clapeyron (which can be expressed as $\log p = A + B/T$, where A and B are constants). Other substances, for example, mercuric chloride, propylene and diethylene glycols, apparently require to be of an approximately similar concentration. Notable exceptions are iodine and maleic anhydride (below 1 per cent), suggesting that the mechanism of the lethal effect here is different from that of the phenols. It will thus be understood that while we see no reason to alter our opinion[4] regarding the fundamental importance of the vapour pressure of phenols in relation to activity on air-borne bacteria, it appears that this particular characteristic is not a reflexion of the activity of all groups of substances. Again, we do not consider water solubility an essential

characteristic, seeing that the fifteen phenols tested varied greatly in this respect.

Occurrence of Strontium in Molluscan Shells

ATTENTION was recently directed to the possible role of small quantities of strontium carbonate in promoting the formation of aragonite, rather than calcite, in certain molluscan shells[1]. At that time the presence of traces of strontium had been demonstrated in only a few species of bivalves with aragonite shells (namely, *Tellina tenuis*, *T.* (*Macrotoma*) *baltica* and *Donax vittatus*), while the absence of strontium from some examples of the calcite shell of *Ostrea edulis* was also recorded.

I have lately had an opportunity of examining spectroscopically the occurrence of strontium in a number of other shells. It may be useful to record these results. The presence of strontium has been noted in the aragonite shells of the following species: *Venus gallina*, Gower, South Wales; *Lutraria elliptica*, Clyde; *Ceratisolen legumen*, South Wales; *Arca tetragona*, Naples (traces only); *Mactra stultorum*, South Wales (traces only); *Tellina fabula*, Aberdeen (traces only); *Cyprina islandica*, Clyde; *Pholas crispata*, ? Clyde; *Tapes aureus*, West Loch, Tarbert; *Dentalium entalis*, ? Inner Hebrides; *Nautilus* sp.; *C. edule*, Fairlie, Clyde, Scilly Isles, South Wales (traces only); *C. edule*, Cannes (more distinct).

No evidence of strontium was observed in the following aragonite shells: *Cardium echinatum*, Clyde; *Nucula tenuis*, Clyde; *Unio* sp., New Zealand: *Dreissensia polymorpha*, canal at Possil, Glasgow.

No evidence of strontium was obtained in the calcite shell *Anomia ephippium* from the Clyde. Slices of two species, *Mytilus edulis* from the Clyde, and *Pecten varius* from the Clyde, which include layers of both calcite and aragonite were examined, the layers being crushed together. No trace of strontium was obtained in either species.

It may be concluded that small traces of strontium are commonly found in shells consisting of aragonite, but that its occurrence is not universal, and though it may be one of the factors leading to the formation of aragonite, other factors must also be involved. Comparatively few calcite shells have yet been examined, but no evidence of strontium has been obtained in any of them.

My thanks are due to Prof. E. Hindle and Mr. R. Elmhirst for some of the material examined, and to Prof. J. W. Cook for facilities for spectroscopic examination.

Achilles and the Tortoise: a Variant

ZENO's famous paradox might perhaps be used in the following way to enliven young aspirants condemned to listen to a bald narration of the peculiar virtues of the exponential function. Assuming Achilles to give the tortoise a flying start of 10 units and to move always ten times as fast as the tortoise, every schoolboy (untroubled by the infinite divisibility of space and time that formed the basis of Zeno's argument) knows that Achilles will overtake the tortoise when the latter has moved $1\frac{1}{9}$ units from its starting-point, and that this result is independent of the absolute and constant speeds of Achilles and the tortoise. Now for the enlivenment (?). Let us suppose that both Achilles and the tortoise suffer from immediate and continuously increasing fatigue, in such a manner that $v_T = pe^{-\lambda t}$, $v_A = 10pe^{-\lambda t}$. It will be observed that the initial ($t = 0$) speeds are p and $10p$ respectively, and that Achilles *always* moves ten times as fast as the tortoise (p and λ are finite positive constants, t denotes time from the start, and the suffixes A and T refer to Achilles and the tortoise respectively). Supposing Achilles to give the tortoise a flying start of 10 units, and t_m to be the time interval from the flying start when Achilles overtakes the tortoise; then

$$10p\int_0^{t_m} e^{-\lambda t}dt - p\int_0^{t_m} e^{-\lambda t}dt = 10.$$

This equation reduces to $e^{-\lambda t_m} = \dfrac{9p - 10\lambda}{9p}$, so that $t_m = \infty$ if $9p = 10\lambda$ or $\lambda = 0 \cdot 9p$. Hence, if the latter relation holds between the constants λ and p, Achilles will, in ordinary language, never overtake the tortoise. It will be observed, however, that even in the infinite limit, the distance traversed by the tortoise would still be $1\frac{1}{9}$ units, since this distance is p/λ when $t_m = \infty$. In order to avoid undue levity among the aspirants, it might be better to substitute a second tortoise for Achilles.

Post-War University Education

MR. HARDIE's valuable letter in NATURE of January 8 mentions the proposal of the British Association Committee on Post-war University Education that English universities should offer, in addition to the existing specialized Honours Schools, a general honours course in "philosophy, natural and social". Mr. Hardie truly observes that the new discipline would not solve the difficulty of ensuring that students in existing honours groups should acquire "a more balanced and mature mental outlook". But the Committee is now engaged upon this problem; and the draft of a section of its final report, suggesting how the problem might be solved, is to be considered at the next meeting of the Committee. This draft has a good deal in common with Mr. Hardie's own proposal.

AN UNAMBIGUOUS METHOD OF AVOIDING DIVERGENCE DIFFICULTIES IN QUANTUM THEORY

By PROF. E. C. G. STUECKELBERG
University of Geneva

THE classical theory of a point charge and the quantum theory of wave packets contain in their usual form well-known divergences. Dirac[1] has elaborated a classical particle theory which avoids these difficulties, but his results cannot as yet be applied to quantum theory. On the other hand, Heisenberg[2] has recently proposed a new formalism which permits the calculation of collision cross-sections in quantum theory without being disturbed by diverging terms. However, no connecting link such as the correspondence principle has been given in order to apply this quantum formalism to a given problem such as Rutherford scattering, Compton effect or radiation damping.

Dirac's theory being well known, we content ourselves with recalling briefly the general idea of Heisenberg's description of collision phenomena. If no reaction between particles takes place, the behaviour of the system of particles can be described by a plane wave in configuration space $\Psi^{(0)}$. Such a wave can always be decomposed into an incoming $\Psi^{(0-)}$ and an outgoing $\Psi^{(0+)}$ spherical wave. If reactions take place, the number of particles scattered in a given direction (as observed by an observer at infinite distance from the collision region) is determined by a change of phase in the outgoing wave. This effect is described by a unitary phase operator $e^{-i\eta}$ determining the true outgoing spherical wave $\Psi^{(+)} = e^{-i\eta}\Psi^{(0+)}$ at infinity. The operator η must be Hermitic and relativistically invariant. Applying the method to quantized fields $u(\vec{x},t)$, Heisenberg discusses the effects due to η values of the form

$$\eta = \varepsilon \int_{-\infty}^{+\infty} dt \int (dx)^3\, u\left(\vec{x},t\right)^n.$$

If u is written as a series
$u = \Sigma\, (2Vk^4)^{-\frac{1}{2}} (a_k \exp(i(k,x)) + a_k^* \exp(-i(k,x)))$
with $(k,x) = (\vec{k},\vec{x}) - k^4 t$, $k^4 > 0$, the operator η has to be chosen so that all the a^*'s stand left of all the a's. This rule is invariant and prevents singularities from occurring. The space-time integral guarantees the invariance of the formalism and implies the usual conservation laws of energy (k^4) and momentum $\vec{k}$. No description for finite distances is possible in this theory.

We have succeeded in connecting the usual quantum theory to the Heisenberg formalism, and the result is but the logical translation of Dirac's classical theory into quantum language. Our method will best be understood in the following example: Let $u(x) = u(\vec{x},t)$ be a field of matter (particles) the wave packets of which follow the same world-lines $x^\alpha = q^\alpha(\lambda)$ as the particles do. If $m\,\ddot{q}_\alpha = \varepsilon\partial\varphi/\partial q^\alpha$ is the differential equation of the corresponding particles in a given field of force $\varphi(\vec{x},t)$,

$$(\Box - (m^2 - 2\varepsilon m\varphi))\,u = 0 \qquad (1)$$

is the wave equation. The reaction on the field φ is described by

$$(\Box - \varkappa^2)\,\varphi = -\rho;\ \rho = \varepsilon m u^2;\ (\text{or} = \varepsilon \int d\lambda\, \delta(x - q(\lambda)))\ . \qquad (2)$$

In quantum theory we treat both u and φ as operators, developing them into series with a_k^*, a_k (for u) and b_μ^*, b_μ (for φ). Thus, the explicit time dependence of u and φ is given by $(\Box - m^2)u = (\Box - \varkappa^2)\varphi = 0$, while the true time derivative $\dot{u}$ follows from a canonical formalism

$$\dot{u} = \frac{\partial}{\partial t} u\left(\vec{x},t\right) + i\varepsilon\left[H(t), u\left(\vec{x}\,t\right)\right];$$
$$\varepsilon H(t) = \varepsilon m \int (dx)^3 \varphi u\left(\vec{x},t\right)^2 \qquad (3)$$

This expression (3) and the explicit time dependence of the operators are equivalent to (1) and (2). In order to apply our theory to an actual problem, we have to express the Schrödinger probability amplitude $\Psi(t)$ in terms of the probability amplitude $\Psi(-T)$ at a time $t = -T$ before the collisions have occurred ($\lim T = \infty$). Quantum theory proceeds as follows: the Schrödinger differential equation

$$\frac{\partial\Psi(t)}{\partial t} = -i\varepsilon\, H(t)\, \Psi(t) \qquad (4)$$

is solved by successive approximations in ε. We try, however, the solution

$$\Psi(t) = e^{\alpha(t)}\, \Psi(-T). \qquad (5)$$

Substituted into (4), it leads to the integral equation $(\partial\alpha/\partial t \equiv \dot{\alpha})$

$$-iH(t) = \dot{\alpha}(t) + \frac{\varepsilon}{2!}[\alpha, \dot{\alpha}] + \frac{\varepsilon^2}{3!}[\alpha,[\alpha,\dot{\alpha}]] + \ldots \qquad (6)$$

In order to obtain a solution for the unknown operator $\alpha(t)$ ($\alpha(-T) = 0$), we develop $\varepsilon\alpha$ in the following series $\varepsilon\alpha = \varepsilon\alpha^{(1)} + \varepsilon^2\alpha^{(2)} + \varepsilon^3\alpha^{(3)} + \ldots$

The first terms are

$$\begin{aligned}
\varepsilon\dot{\alpha}^{(1)} &= -\,i\varepsilon H(t) \\
\varepsilon^2\dot{\alpha}^{(2)} &= -\frac{\varepsilon^2}{2}[\alpha^{(1)}, \dot{\alpha}^{(1)}] \equiv \varepsilon^2 \alpha \overset{(2)}{R} + \varepsilon^2 \alpha \overset{(2)}{C} \\
\varepsilon^3\dot{\alpha}^{(3)} &= -\frac{\varepsilon^3}{2}[\alpha^{(2)}, \dot{\alpha}^{(1)}] - \frac{\varepsilon^3}{6}[\alpha^{(1)}, \dot{\alpha}^{(2)}]
\end{aligned} \qquad (7)$$

etc. Integrating from $-T$ to t and applying the usual commutation rules ($[u(x), u(y)] = iD(x-y)$), the first terms are

$$\begin{aligned}
\varepsilon\alpha^{(1)} &= -\,i\varepsilon m \int_{-T}^{t} dt \int (dx)^3 u^2\varphi\left(\vec{x},t\right) \\
\varepsilon^2\alpha \overset{(2)}{R} &= -\,i\,\frac{\varepsilon^2}{2} m^2 \int_{-T}^{t} dt \int (dx)^3 u\left(\vec{x},t\right)^2 \operatorname{ret}_{(\varphi)}(u^2) \qquad (8) \\
\varepsilon^2\alpha \overset{(2)}{C} &= -\,i\varepsilon^2 m^2 \int_{-T}^{t} dt \int (dx)^3 u\varphi\left(\vec{x},t\right) \operatorname{ret}_{(u)}(u\varphi) \\
\varepsilon^3\alpha^{(3)} &= -\,i\varepsilon^3 m^3 \int_{-T}^{t} dt \int (dx)^3 (u\left(\vec{x},t\right)^2 \operatorname{oper}(uu\varphi) + \ldots).
\end{aligned}$$

$\operatorname{ret}_{(\varphi)}(\rho)$ is the retarded potential of a charge density ρ in (2), oper (ρ) is another more complicated integral operator. After developing u and φ in terms of the a, a^* and b, b^* operators, we can, as did Heisenberg, interchange their order so as to have all a^*, b^* left of the

a,b. This change corresponds to an invariant subtraction of all diverging terms; the term $a^*_{k''}a_{k'}\,a^*_{k'}\,a_k$ in $\alpha_C^{(2)}$ contributes to the 'Coulomb' self-energy of the u-particles. The other terms of $\varepsilon^n\alpha^{(n)}$ correspond to the transition-probabilities for collisions in which $n + 2$ particles take part (in the sense of chemical reactions). For example, $\varepsilon^2\alpha^{(2)}{}_R$ contains the term $a^*_{k'''}a^*_{k''}a_{k'}a_k$, where two particles with the momenta k and k' disappear and two particles of momenta k'' and k''' are created. This is Rutherford scattering (if φ is the electromagnetic field) and $\varepsilon^2\alpha^{(2)}{}_C$ contains the Compton effect $(a^*_{k'}b^*_{\mu'}a_kb_\mu)$, where a φ-quantum of momentum μ collides with a u-particle of momentum k. The terms in $\varepsilon^3\alpha^{(3)}$ contain the *Bremstrahlung* $(a^*_{k'''}a^*_{k''}\,b^*_\mu a_{k'}a_k)$, where, in addition to the Rutherford scattering, a μ-quantum is created.

Putting $t = +T$ and passing to $T \to \infty$, our theory takes the Heisenberg form. However, we have unambiguously determined the Hermitic Heisenberg operator $\eta = i\varepsilon\alpha(\infty)$ and, furthermore, for any given t, we can describe the quantum mechanical state of the system.

We can arbitrarily change the numerical coefficients of each individual $\varepsilon^n\alpha^{(n)}$ (or of their invariant parts) without destroying the conservation laws or the invariance. For example, a theory which contains only $\varepsilon\alpha = \varepsilon^2\alpha^{(2)}R$ and nothing else shows Rutherford scattering but no radiation effects (no Compton effect and no *Bremstrahlung*, etc.). But such a theory is possible even classically. Consider a system of particles, where the force acting upon any one of them is the mean value between the advanced and retarded effect of all other particles. Such a theory is invariant and conserves energy and momentum, but it is not conformal to our causal representation of phenomena. The same acausal behaviour is contained in the quantum mechanical $\Psi(t)$. There exists now a finite probability that a quantum appears at a certain event $(\vec{x},t)$, without a finite probability that a cause has occurred at a preceding event in the invariant past of $(\vec{x},t)$. In electrodynamic phenomena, the causal behaviour has been experimentally checked. Therefore, our theory is unambiguous if applied to quantum electrodynamics. Applied to nuclear forces, however, we have great liberty in the choice of $\varepsilon\alpha$ (or of Heisenberg's η) if we go back to a causal description at small distances. But one must say that it is not necessary to go back to causal description even for distances of 10^{-13} cm.

We have applied our theory to the case of line width. A classical point particle with an internal (scalar) degree of freedom (τ, ρ, σ) treated according to Dirac's method leads to

$$\ddot{\tau} + \frac{1}{2\pi}\,\varepsilon^2\mu_0\,\sigma\dot{\tau} + \mu_0{}^2\tau = \varepsilon\sigma\,\varphi\,(q(\lambda))^{\text{inc}};\ \dot{\sigma}\sim 0.$$

Its line broadening due to radiation damping is (if $\sigma = +1$ and $\varkappa = 0$) therefore

$$J(\mu) = \gamma^2\,((\mu - \mu_0)^2 + \gamma^2)^{-1};\ \gamma = \frac{\varepsilon^2}{4\pi}\,\mu_0. \qquad (9)$$

The corresponding quantum mechanical model is given by two fields of matter u and v the rest masses of which differ by $m_v{}^2 - m_u{}^2 \cong 2m\mu_0$. With $\varepsilon H = 2\varepsilon m\int(dx)^3 uv\varphi$, only particles of mass $m_u (< m_v)$ are stable (analogous to $\sigma = +1$ in classical theory). Excitation of the u-particle into the v-state and subsequent emission of a φ-quantum, or the dispersion of a φ-wave produces φ-quanta of frequency μ with a probability given by

$$J(\mu) = \left(\sin\frac{\gamma}{\mu - \mu_0}\right)^2;\ \gamma = \frac{\varepsilon^2}{4\pi}\,\mu_0 \qquad (10)$$

instead of (9). This is a rigorous solution of the quantum-mechanical problem. The approximate treatment of Wigner and Weisskopf[3] leads to (9). Total intensity of the emitted light and the dispersion for $|\mu - \mu_0| \gg \gamma$ are, however, the same.

BEHAVIOUR OF THE SONG SPARROW AND OTHER PASSERINES

MRS. NICE is well known to ornithologists as an indefatigable and scientific observer, whose previous detailed studies on the song sparrow (*Melospiza melodia*), published in 1937 as vol. 4 of the *Transactions of the Linnæan Society of New York*, had shed new light on the detailed behaviour of particular individuals of a particular bird species in Nature, as well as extending our general ideas on the territory theory. In a second work* she brings together under their various heads the behaviour traits of the song-sparrows she has watched in Nature and those she has hand-reared herself (all her observations concern colour-banded and therefore individually recognizable individuals), together with a vast amount of data on other species from the recent literature. Thus we have here one of the first essays in the comparative study of avian behaviour.

The result is of great value. Methodologically it is of interest as a crowning demonstration of the fact that field observation, if properly carried out, is an essential tool of biological science: laboratory research could never have elicited the facts and principles here set before us. It is also a reminder for the average biologist that the principles of vertebrate behaviour are now emerging with some clarity, thanks very largely to the labours of field ornithologists, and that they are in many ways unexpected and of great general interest.

It is impossible in the space available to give a critical review, and I must confine myself to citing some of the chief topics covered by Mrs. Nice, with the reminder that in each case she gives a balanced discussion of her own and others' findings.

These topics include an attempt to disentangle innate and acquired factors in bird behaviour (which leads to somewhat surprising results); a general discussion of Lorenz's basic theories of *releaser* or *signal* stimuli, and of the role of the *Kumpan* (or fellow-member of the same species) in the social life of birds; an account of the genetic psychology of passerine birds from hatching onwards; waking and sleeping times in relation to twilight; a discussion of the dominance and subordination relations of passerines; 'symbolic' actions; song; territory; habitat selection; a general analysis of the difficult problems of pair-formation; courtship; injury-feigning; enemy recognition; individual variation in behaviour.

* "Studies in the Life History of the Song Sparrow (2). The Behavior of the Song Sparrow and other Passerines". By Mrs. M. M. Nice. (*Trans. Linn. Soc., N.Y.*, 6, Sept. 1943, pp. viii+329.)

In regard to this last point, Mrs. Nice makes it clear that every individual male song-sparrow has his own repertoire of songs, all of them readily distinguishable, with a little practice, from those of all other males. The number of separate songs in a cock bird's repertoire varies from six to twenty-four. One male song-sparrow sang from 4.45 a.m. to 7.43 p.m., giving 2,305 songs in fifteen hours, with 278 songs as his highest rate per hour!

Again (as Lack has since shown in the English robin) migration is a matter of individual variation; and indeed birds that migrate one year need not do so the next.

There are a few criticisms to be made. Among several misprints (including some, such as the transposition of lines on p. 64, which one does not expect to find in a scientific publication), there is one serious one in Table 13 where *songs* should apparently be *song-series*; and in Table 5, the "group V" discussed in the text is omitted. Although a great volume of literature is comparatively reviewed, there are some curious and unexplained gaps. Thus, though Lloyd Morgan's fundamental "Habit and Instinct" and Kirkman's recent important studies on egg and nest-site recognition are cited in the literature list, they appear to be neglected in the discussion. The important work of Lockley on homing and other activities in shearwaters is entirely omitted, together with the numerous data of various authors on the behaviour of the gannet, and the valuable work of Nicholson and Koch, complete with gramophone records, on the song of British birds. More generally, the sections on courtship and display might have been fuller, with more weight given to studies on other forms, notably non-passerines.

These, however, are mere minor omissions. The work as a whole is a monument of industry and a model of method. If the author appears to go a little far in claiming (p. 273) that "the study of animal behavior is the only and ultimate source of understanding ourselves", it is certainly true that it is an indispensable aid in that task, and further that it reveals unexpected aspects of mental evolution which even the most complete study of our own psychological organization could not have made available. In any event, in this and the preceding work, Mrs. Nice has made a massive and outstanding contribution to our advancing knowledge of animal behaviour. JULIAN HUXLEY.

OX BLOOD FOR BLOOD TRANSFUSION

MANY people must have wondered whether some use could not be made of the large quantities of ox blood available in our slaughter-houses. If the conclusions drawn by Dr. Edwards (*Brit. Med. J.*, Jan. 15, 1944) and his collaborators survive the further tests to which they are being subjected, the ox of the future may not only give his life and meat for man, but may serve him also with his very blood and may be kept for that purpose by the community.

The use of plasma for surgical treatment is, as Dr. Edwards points out, increasing rapidly, and the search for a suitable plasma other than that provided by the blood banks is in progress. It would seem that the collaboration between Dr. Edwards and the Regional Transfusion Laboratories, the North Staffordshire Royal Infirmary and experts at Cambridge and Liverpool, has gone a long way towards the solution of this problem. The substitutes for human plasma which have been tried have not, Dr. Edwards states, possessed the three characteristics that are necessary, namely, that they should be retained in the circulation and should eventually be metabolized, that they should exert an osmotic pressure equivalent to that of the plasma and that they should be non-toxic, free from antibodies and non-antigenic. Bayliss in 1916 tried 6 per cent gum acacia in saline for the treatment of shock, but this was only partially metabolized and much of it remained in the tissues with unpleasant consequences. Other substances mentioned by Dr. Edwards may maintain the blood-pressure in shock and hæmorrhage, but they do not restore the blood protein. Animal plasma protein most nearly resembles human plasma protein, and the total protein of bovine blood most nearly approaches that of human blood; but it contains a much higher percentage of fibrinogen. Further, its albumin/globulin ratio is lower, so that bovine blood might exert a lower osmotic pressure, because the albumin fraction exerts the greater pressure. Bovine blood is, however, available in practically unlimited quantities.

It has been shown that crude bovine serum is unsuitable. Dr. Edwards outlines the attempts to overcome such difficulties as the serum sickness which it causes and the tendency to hæmolysis of the human red cells and the slow rate of administration. He explains in detail the method which he and his collaborators have finally adopted for the preparation of a bovine serum which has been tested on twenty-six cases. The method includes the heating of the serum to 72° C. to destroy the antibodies and the addition of 0·2 per cent of formalin and ammonia to render the proteins uncoagulable. He claims that the serum obtained fulfils the requirements indicated above.

The final product is called D.B.S. (despeciated bovine serum). It has an osmotic pressure comparable to that of filtered human plasma. It was kept for six months in Dr. Edwards's car and was then given to a patient without untoward results; after nine months in a refrigerator it had not deteriorated. It can, moreover, be given very rapidly and in large amounts. After a preliminary trial on twenty-six patients, Dr. Edwards claims that it is safe to give it to man and that it is well retained in the circulation. It is easily prepared in large quantities.

The possibility of the transmission by it of tuberculosis or of *Brucella abortus* has been considered. Dr. Edwards advocates bleeding from tuberculin-tested stock only; or only from bullocks and heifers, because only 6 per cent of these coming to the slaughter-house are infected with tuberculosis or *Brucella abortus*, whereas the rate among slaughtered cows is 30 per cent. If the meat inspector reports gross tuberculous infection of the carcass, the blood taken from that animal should be discarded. But the Seitz filtration during the process of manufacture should, Dr. Edwards thinks, remove any of these organisms that may be present in the blood.

Before he gives a final judgment, Dr. Edwards wisely awaits the results of more detailed hæmatological and biochemical work on the effects of the administration of despeciated blood serum to patients in states of shock, hypoproteinæmia and protein deprivation and loss. G. LAPAGE.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Saturday, January 29

ROYAL PHOTOGRAPHIC SOCIETY (SCIENTIFIC AND TECHNICAL GROUP) (joint meeting with the ASSOCIATION FOR SCIENTIFIC PHOTOGRAPHY) (at 16 Princes Gate, South Kensington, London, S.W.7), at 2.30 p.m.—Symposium on "Micro-densitometry and Micro-sensitometry".

Tuesday, February 1

INSTITUTE OF FUEL (at the Institution of Electrical Engineers, Savoy Place, Victoria Embankment, London, W.C.2), at 2.30 p.m.—Mr. Harold Moore: "Liquid Fuels and Organic Chemicals from Coal and Home-Refined Petroleum".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Prof. H. D. Kay: "Modern Developments in Dairy Science", ii. "Milk Production and Livestock Problems".*

INSTITUTION OF CIVIL ENGINEERS (ROAD ENGINEERING DIVISION) (at Great George Street, Westminster, London, S.W.1), at 5.30 p.m.—Mr. R. U. Law: "Modern Plant and Road Construction".

Wednesday, February 2

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. E. C. Goldsworthy: "Light Alloys in Post-War Britain".

Thursday, February 3

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Sir Lawrence Bragg, F.R.S.: "The Strategy and Tactics of Crystal Structure Analysis by X-Rays".*

KING'S COLLEGE (in the Department of Electrical Engineering, Strand, London, W.C.2), at 3 p.m.—Mr. W. D. Horsley: "Turbo Generator Practice".*

Friday, February 4

SOCIETY OF CHEMICAL INDUSTRY (MANCHESTER SECTION) (joint meeting with the NORTHERN BRANCH OF THE INSTITUTE OF PETROLEUM) (at the Grand Hotel, Aytoun Street, Manchester), at 2.30 p.m.—Dr. F. King: "Petroleum Refining—a Chemical Industry".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5 p.m.—Prof. E. D. Adrian, O.M., F.R.S.: "Brain Rhythms".*

NORTH-EAST COAST INSTITUTION OF ENGINEERS AND SHIPBUILDERS (at the Mining Institute, Newcastle-upon-Tyne), at 6 p.m.—Mr. S. Booth: "The Electrical Equipment of Ships".

Saturday, February 5

NUTRITION SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 10.30 a.m.—Conference on "Budgetary and Dietary Surveys of Families and Individuals", Part 1.

GEOLOGISTS' ASSOCIATION (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Sir Edmund O. Teale: "The Geology and Scenery of Tanganyika Territory, East Africa".

INSTITUTE of PHYSICS (MANCHESTER AND DISTRICT BRANCH) (at the Christie Hospital and Holt Radium Institute, Wilmslow Road, Withington, Manchester), at 2.30 p.m.—Prof. W. V. Mayneord: "Physical Principles of X-Ray Therapy".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ORGANIZER OF AGRICULTURAL EDUCATION—The Secretary for Education, County Hall, Ipswich (February 1).

ASSISTANT HORTICULTURAL OFFICER (temporary)—The Executive Officer, Berkshire War Agricultural Executive Committee, 1 Abbot's Walk, Reading (February 4).

ASSISTANT (temporary) TO THE ADVISORY BACTERIOLOGIST—The Secretary, Edinburgh and East of Scotland College of Agriculture, 13 George Square, Edinburgh (February 5).

LECTURER IN CHEMISTRY—The Clerk and Treasurer, Dundee Institute of Art and Technology, Bell Street, Dundee (February 5).

PRINCIPAL of the Gloucestershire College of Domestic Science and Training College—The Secretary, County Education Office, Shire Hall, Gloucester (February 5).

CHIEF TOOL DESIGNER for service in an Admiralty Establishment in Scotland—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. C.1965.A.) (February 9).

METALLURGIST AND CHEMIST in a large general purpose Iron Foundry and Engineering Works in the North Midlands—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. O.N.F.1932.XA) (February 9).

LECTURER IN PHYSIOLOGY—The Registrar, King's College, Newcastle-upon-Tyne (February 9).

REGISTRAR—The Principal, University College of Wales, Aberystwyth (February 10).

TUTOR IN NATURAL SCIENCE—The Principal, Lady Margaret Hall, Oxford (February 10).

HEAD OF THE DEPARTMENT OF CHEMISTRY AND BIOLOGY of Leeds College of Technology—The Director of Education, Education Office, Leeds 1 (February 12).

INSTRUCTOR (temporary) IN TECHNICAL SUBJECTS at the Hull Nautical School and School for Fishermen—The Director of Education, Education Offices, Guildhall, Hull (February 14).

RADIOGRAPHER in charge of the X-Ray Department and PRINCIPAL of the School of Radiography—The House Governor, King's College Hospital, Denmark Hill, London, S.E.5 (February 14).

ENGINEERING LECTURER (Ref. No. C.1997A), MATHEMATICS LECTURER (Ref. No. A.422A), PHYSICS LECTURER (Ref. No. A.423A), ASSISTANT MATHEMATICS AND PHYSICS LECTURER (Ref. No. A.424A), ENGINEERING INSTRUCTOR (Ref. No. O/N.391), and a DEMONSTRATOR to assist lecturers in class work generally, for the Technical School of a Government Department located in Surrey—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting the appropriate Ref. No.) (February 16).

CHAIR OF BOTANY tenable at King's College, and CHAIR OF BOTANY tenable at Birkbeck College—The Academic Registrar, University of London, c/o Richmond College, Richmond, Surrey (February 21).

LECTURER IN CHEMISTRY FOR MEDICAL STUDENTS—The Acting Secretary, University Court, Glasgow (February 25).

UNIVERSITY CHAIR OF ANATOMY tenable at St. Mary's Hospital Medical School—The Academic Registrar, University of London, c/o Richmond College, Richmond, Surrey (March 20).

TECHNICIAN to undertake routine preparation of slides and to assist in research in the Department of Physiology—Prof. Burns, Medical School, King's College, Newcastle-upon-Tyne, 2.

PHYSICAL-CHEMIST to work on Adhesives, and a PHYSICIST for work on the Printing Qualities of Paper—The Director of Research, Printing and Allied Trades Research Association, 101 Princes Gardens, Acton, London, W.3.

TWO ORGANIZING SECRETARIES (fluent in two languages, with science degree or scientific background)—The British Council, 3 Hanover Street, London, W.1 (marked 'Science Department').

LABORATORY ASSISTANT (male or female) (B.Sc. with a knowledge of bacteriology and chemistry preferred)—The Pathologist, Cumberland Infirmary, Carlisle.

SCIENTIFIC ASSISTANT for the East African Agricultural Research Station at Amani, Tanganyika Territory—The Ministry of Labour and National Service, Appointments Department, Sardinia Street, Kingsway, London, W.C.2 (quoting Order No. O.S.19).

LECTURER IN MECHANICAL OR ELECTRICAL ENGINEERING, and a SCIENCE LECTURER—CHEMISTRY and/or PHYSICS with subsidiary Mathematics, at the Swansea Technical College—The Director of Education, Education Department, Guildhall, Swansea.

GRADUATE MISTRESS (MATHEMATICS) for Barrett Street Technical School, Oxford Street, London, W.1, and Maidenhead—Application Form T.1/40 from the Education Officer (T.1), County Hall, Westminster Bridge, London, S.E.1.

PSYCHIATRIST (part-time) and an EDUCATIONAL PSYCHOLOGIST (part-time) at Child Guidance Clinics to be established by the Kent Education Committee—The School Medical Officer, Public Health Department, County Hall, Maidstone, Kent.

RELATION OF RELIEF TO RECONSTRUCTION

THE importance of the agreement setting up a United Nations Relief and Rehabilitation Administration and defining its constitution and functions, which was signed by representatives of forty-four countries at Washington on November 9, is not easily overstressed. It is a milestone in the working out of joint post-war policy. It is the first piece of executive machinery to be established, and although it covers a comparatively limited field, it foreshadows a general pattern of post-war co-operation.

The agreement creates a Council representing all member Governments, including "national authorities" like the French, which will lay down general policies and constitute standing committees, including one on supplies, one for Europe, and another for the Far East. Of this Council Mr. Dean Acheson has been elected permanent chairman. Mr. Herbert Lehman, former governor of New York, has been appointed director-general of the United Nations Relief and Rehabilitation Administration with full power and authority to carry out the relief operations contemplated. There is a Central Committee consisting of representatives of China, the Soviet Union, Great Britain and the United States, and regional committees will be appointed by the Council as required. While the relations between the Council and this Central Committee have not yet been clearly explained, on paper the latter does not override.

The new organization is to arrange measures for the relief of war victims through the provision of food, fuel, clothing, shelter, and basic necessities generally, and medical and other essential services. Its task is thus threefold. First, the organization has to build up stores of foodstuffs and other supplies; secondly, it has to see that the available supplies are distributed equitably and efficiently as the opportunity arises; and, thirdly, it has to link relief and rehabilitation so as to encourage self-help and end the need for relief by reviving production.

The admirable series of studies recently issued by the League of Nations offers not only evidence as to the imperative need for the establishment of such an organization but also guidance and warning as to the measures to be taken. We have now an opportunity to do better than in the years following 1918 although in far worse circumstances, but only on condition that we profit by the experience so painfully gained after the last War. The stock position then was much better than it can possibly be at the end of this War: the general food shortage which threatens to face the world is far from being widely appreciated, and in addition there will probably be an acute shortage of fuel and transport. The destruction and dislocation to be overcome are on a far greater scale. It has been estimated that there will be 21,000,000 displaced people in Europe, while in Asia the numbers are even larger: evacuees in China alone have been variously put between thirty and sixty millions.

The magnitude of the task which confronts the new organization is well illustrated by a recent

report for the International Labour Office by Prof. E. M. Kulischer on "The Displacement of Population in Europe", which has just been published*. To minimize the suffering, which the report also discloses, and that which is yet to come before these victims of war can find a useful settled life in a world at peace, is at least as cogent and urgent a reason as the accelerated pace of the War to advance as much as possible our preparations to relieve the needs of the occupied countries as they are liberated. It can equally inspire that sterner and supreme effort in the prosecution of the War itself, so as to hasten the day of liberation and set the shortest possible term on the suffering involved with each day the War continues.

There could be no greater mistake than to regard the proceedings of the Conference at Atlantic City in working out the technical implications of the agreement—how much food, clothing, medical and other supplies will be needed, where they are to come from, and how they are to be allocated—as any distraction from our war effort. Such deliberations are a practical test of our fitness to win the War, of the spirit in which the nations will face the problems arising out of the War and the peace. Success can only come if political and national considerations are put firmly on one side and the supplies available made a common pool upon which the most urgent needs have the first call.

The past few months have made clear some of the difficulties that lie ahead. In place of the plentiful supplies at one time anticipated, only the most careful husbanding, especially of food, will ensure that supplies are adequate. In each country it will be necessary to control and allocate goods which are scarce, taking account of the needs of the War, of its own civilian population, and of the victims of German ruthlessness. For this reason alone the Relief Administration will require strong backing to enable it to succeed. The representatives must be men who carry weight in their own country, in order to induce their fellow-countrymen to submit to the necessary sacrifices for the common good. Every effort, too, must be made to secure the full understanding of what is involved and why such sacrifices are necessary. Firm backing will also be necessary to secure equality. Liberated countries with funds must not be allowed to secure preferential treatment over others. Countries liberated first must be prevented from scrambling for goods, to the loss of countries to be freed later.

All this implies control of imports and of shipping and much international self-denial. This cannot be expected without a carefully planned programme of education. Moreover, the Relief Administration has to continue all the work that has been done in preparing for economic rehabilitation; and the high degree of technical skill required makes it essential that it should not be starved of either staff or money. Here, as in other matters, this first concrete step in world co-operation will speedily provide a searching test of our sincerity and determination to build a better world order and to profit by past mistakes and bitter experience.

There are reasons why the United Nations Relief and Rehabilitation Administration conference somewhat overshadows the Food and Agriculture Conference at Hot Springs earlier last year. The latter was concerned with long-term post-war policies; the former is concerned with the more immediate problems that will arise, first in Europe and then in the Far East. What we have already said indicates that the new Administration may be the most important executive agency in international reconstruction. From it will proceed the first steps in international co-operation for peaceful ends. Its work is necessarily tied up with all the wider problems of agriculture, currency, commercial policy, commodity control, transport, etc., on which common action by the United Nations is planned.

It is therefore of special interest to note that the proposed organization appears to embody the functional principle advocated so ably by Dr. D. Mitrany, as well as the regional principle represented for war purposes in the Middle East Supply Council and the Anglo-American Caribbean Commission. How far this pattern may determine that of post-war international co-operation generally remains to be seen, but experience gained during the War appears to be turned to account and there is less reason to fear that, this time, machinery established to further our war effort will be scrapped without forethought. The success of this practical test of our ability to co-operate may well have a profound effect not only on co-operation in other fields but also on economic and commercial policy and post-war trade generally (see p. 159 of this issue).

A notable example of the educational work required to ensure the success of the work of the Relief and Rehabilitation Administration is provided by the symposium on post-war problems arranged last February by the American Philosophical Society*. Mr. G. S. Ford's paper, "America Enters the Scene", with its note on the need for self-education and discipline if we are to solve the problems of post-war settlement and establish an economy providing the greatest possible freedom of interchange of raw materials and the finished products of men's hands and minds, could have been delivered as pertinently to a British as to an American audience. The same might be said of F. G. Boudreau's analysis of the social and economic implications of freedom from want of food, with its reminder that adoption now of adequate nutrition policies by the Governments of the United Nations would provide an expanding market for agricultural products for years to come, and that a sound nutrition policy would increase the international exchange in foodstuffs rather than diminish it. Evidence of the attitude of the smaller nations is afforded by Alexander Loudon's paper discussing the control of German industry, Halvadan Koht's paper on "The Small Nations in the Post-War World" and Oscar Halecki's paper on the problem of self-determinism, with their emphasis on democracy and on regionalism.

* "The Displacement of Population in Europe". By Prof. E. M. Kulischer. (London: P. S. King and Staples, 1943.) 6s. net.

* *Proc. Amer. Phil. Soc.*, 87, No. 2 (August 16, 1943).

These papers, like Alexander Loveday's paper on "The Economics of Transition", show well the issues involved, and the imperative necessity of international co-operation in the formulation and execution of policies for maintaining full employment. Nor can men of science be blind to the dangers to health and the maintenance of order if we fail to provide the organization to deal with relief and rehabilitation. As the report of the International Labour Office says : "Unless there is an organisation to provide these people with means of subsistence and to give them confidence that they have not been forgotten, the highways of Europe will be blocked by long processions of destitute exiles enduring every kind of privation in an effort to return unaided to their homes".

Here is a task demanding not merely technical knowledge and first-class administration, the training of staff and the mapping out of the field ; but also something akin to an international employment service and the steady co-operation of all the United Nations. On its discharge may well depend the future of European civilization and the rebuilding of the broken centres of learning and research throughout the occupied countries.

HIERONYMUS FABRICIUS, 1533–1619

The Embryological Treatises of Hieronymus Fabricius of Aquapendente

The Formation of the Egg and of the Chick (De Formatione Ovi et Pulli), the Formed Fetus (De Formato Foetu). A facsimile edition, with an Introduction, a Translation, and a Commentary, by Prof. Howard B. Adelmann. Pp. xxiii+883. (Ithaca, N.Y.: Cornell University Press. London: Oxford University Press, 1942.) 12 dollars.

THIS learned and imposing monograph will in the course of time take its place alongside Dobell's "Leeuwenhoek" as one of the classics of the critical and historical literature of biology. We already owe to Prof. Adelmann an important study of the embryological work of Coiter, and he now deals with the similar researches of the famous Padua anatomist. It is to be hoped that in the near future he will complete the trilogy by extending his historical studies to Malpighi, who, as an observer at any rate, is by far the greatest of these three heroic figures. It is true that Malpighi had the assistance of optical equipment not available to the other two, and although he frequently complained of its defects, he was nevertheless enabled to follow out the development of the heart and aortic arches in the chick with a success truly astonishing, and even unparalleled for more than a century after his time.

The plan of Adelmann's work includes the following chapters : life of Fabricius ; sketch of the history of embryology before Fabricius, illustrative of the relevant biological and philosophical environment of the story (necessary in assessing the value of Fabricius's own contributions and the interpretation to be put upon them); analysis of the two embryological works on the chick and the mammal, together with a bibliographical note ; translations of these two works, including ten leaves of explanatory matter accompanying a set of coloured plates in the library of the College of Physicians of Philadelphia (particularly important to most readers to whom the printed works only of Fabricius are available) ; facsimiles of the first editions of the printed versions ; notes and commentary ; literature consulted. There is also an excellent index. The one defect, or rather inconvenience, of this arrangement is the separation of the notes from the text. There are some 1,400 notes, which are not numbered consecutively but in thirty-two series, so that, for example, there are thirty-two notes bearing the number 1, and so on. Searching for the notes, which are much too important to be ignored, takes not a little time, the reader being continually switched over from one part of the work to another, and then back again, with the result that the continuity of the narrative is broken and its thread lost. Even if the harassed reader decides to read the notes separately, the drawbacks are scarcely less formidable.

A fascinating chapter of Adelmann's book is the vivid picture he draws of life in one of the most famous medical schools of Western Europe in the sixteenth century. From it we learn much of Fabricius as a teacher, of his evasions and irregularities, but we hear also of his successes, when he chose to exert himself. We owe to Fabricius, indeed, the earliest and most interesting anatomy theatre extant, now preserved as a national monument, which has been admirably described by Franklin. In this famous room, says Albinus, Fabricius was the first to dissect a human body before a great concourse of spectators. The students themselves were by no means a static factor in the situation. They exercised weighty authority in arranging courses of anatomy with their reluctant professor, nor did they hesitate to comment freely and openly on the result, whether satisfactory or otherwise.

Fabricius himself was more interested in research than in teaching. He was one of the first to emphasize the importance of the comparative approach to anatomical knowledge. His failures were due very largely to the influence of the scholastics, whom he could never bring himself completely to abandon. Nor must we forget that the vision of the pioneer cannot in the nature of things embrace the complete picture, no matter whether he is working in the sixteenth century or the twentieth. His mind is so obsessed with certain of the more obvious and attractive features of the problem under investigation that he neglects others of much greater significance. Not that he is necessarily unconscious of them, but that he fails to recognize their claim on his attention. Fabricius's own scheme of research was admirable, but in carrying it out he allowed Aristotle and Galen to play too large a part in it. If, however, the work of Fabricius is lacking in philosophical interest, it exercised an undoubted influence on the future of anatomical science, and especially on its comparative aspects. The "Fabrica" of Vesalius placed so heavy a premium on human anatomy that animal structure was in danger of neglect. It was left to Coiter, Fabricius and Casserius to restore the balance, not only by their own researches, but also by diverting the labours of others into the more profitable channel.

One anomalous and almost inscrutable feature in Fabricius's writings is that whereas he quotes liberally from his classical authorities, he often completely ignores the work of his contemporaries, even sometimes when it was carried out in his own department, and therefore must have been well known to him. For example, he claims to have seen the tensor tympani muscle in 1599, but Eustachius had

described and figured it in 1563, and the account of it published by Casserius in 1601 was contemporaneous with his own work, and the product of the school of anatomy in Padua. Again, Fabricius went badly astray on the structure of the auditory labyrinth, although the three osseous canals had been described by Fallopius in 1561, and his own pupil Casserius had discovered the membranous labyrinth of the pike in 1600. Such was the tangled mentality of the man which Prof. Adelmann has attempted, with conspicuous success, to unravel.

Fabricius's embryological researches were carried out on man, certain mammals (mostly ruminants), the grass snake, dogfish and the chick. In the chick he discovered the organ now known as the bursa Fabricii, and there are certain observations of value, but the plates are superficial and the general conclusions do not display much searching of the mind. In the mammal, however, he is much more successful, and this elaborate memoir must rank as the first treatise on *comparative* embryology. He was the first to figure and describe *accurately in detail* the cotyledonary placenta of ruminants, the peculiar bifid allantois of the sheep, the foramen ovale and the ductus arteriosus. Prof. Adelmann gives us a meticulously accurate English translation of these two memoirs, and the rendering of the many difficult passages shows that he is unwilling either to admit defeat or to hazard the long shot. We are also grateful to him for the facsimile reproductions, which for the purposes of work are as good as the originals, themselves difficult to obtain and then only at high prices. Prof. Adelmann's analytical commentary is a combination of fine scholarship, sound judgment, and a deep knowledge of the relevant modern research in the subject. It is only when all these conditions are satisfied that so important a book can be produced.

F. J. Cole.

A PHILOSOPHY OF FREEDOM

Religion, Science and Society in the Modern World
By A. D. Lindsay. (The Terry Lectures delivered at Yale University, 1943.) Pp. 64. (London: Oxford University Press, 1943.) 3*s*. 6*d*. net.

THE Terry Lectures at Yale in 1943 have been used not merely to discuss "Religion in the Light of Science and Philosophy", as the Foundation requires, but to do so in the midst of events affecting the Old World and the New to a degree never before experienced. It is such a setting which makes this nineteenth series perhaps more significant than any of its predecessors. Furthermore, Anglo-American relations are closer to-day than they were, and thus the choice of the Master of Balliol as lecturer was indeed a happy one. He recalls the historic connexion between his own College and the Franciscan movement, which stressed the acquisition of knowledge as an instrument of service. From this remark the main theme of these addresses can be discerned, namely, freedom in its connexion with religion, science and power. The strain of the Puritan can be picked up here and there; but the important thing is that the outlook so engendered is very far from negative, though perhaps scarcely everybody would subscribe to all the author's claims for it in the moulding of our traditional institutions. The pressure upon thought to issue in action would have delighted the late Prof. R. G. Collingwood, and may even be taken as yet another vindication of "Speculum Mentis". How easily, however, this urge may go adrift is seen from the fact that in our day a State has arisen wherein there is no place whatsoever for religion, science or philosophy. This is extremely suggestive: these blessings do not perish separately; they are submerged together.

The author notes in some detail our present-day assumption that science will go on indefinitely making discoveries, and adds very truly that in religion is first found the germ of the idea of infinite progress. What is not quite clear, however, is whether or not these two outlooks are trying to envisage the same thing. There is unquestionably a humanistic philosophy which looks forward—in brief—to 'bigger and better' everything. Conversely, nobody can seriously deny that all life on this world must ultimately become extinct, and that therefore the only valid progress is necessarily of a kind transcending purely mundane values. Certainly there is room in plenty for every kind of change and diversity in the meantime, but the massive doctrine of the degradation of energy still stands fast, keeping our eyes on the clock.

The impressive argument of these lectures is pleasantly interrupted for a moment or two here and there to let in something a little lighter. An example is the account of Hobbes becoming a sudden convert to geometry, upon meeting Euclid I, 47, for the first time. This experience happened in middle life, and apparently made him a 'mathematics fan', to continue unabated well beyond his ninetieth year. It is a pathetic little story, but nevertheless much to be wished that certain would-be enthusiasts of all ages and of all kinds would take note of it.

Returning to more serious things, Dr. Lindsay gives one of the best short descriptions of the Cartesian position as we now see it ever likely to be presented in a course of this nature, and goes on to declare "that the modern sciences for all their mathematics cannot do without perception and experiment and do not now want to do without them". Maybe; in fact very likely. But there are at least two most distinguished people, one at each of the ancient universities of Britain, who might rise up and set about this with no mean vigour, should they feel so disposed.

We are now constrained to see—in our day—an almost complete reversal of Descartes, who claimed a high degree of infallibility for science. Infallibility is admittedly not the same as all-sufficiency, but it will nevertheless be convenient to discuss here an important point which the Master of Balliol makes in his last lecture, on power and freedom. It is that one of the causes of our present distress is that students at our universities, on both sides of the Atlantic, have been encouraged to think of science as the be-all and end-all of human needs and affairs, whereas it is manifestly nothing of the sort. There are, we know, vast tracts of life's journey about which it can say nothing. As Prof. Koffka aptly says in his "Gestalt-Psychology", "Must we deny on week-days what we profess on Sundays?" In so far as the tendency exists, this urge to exaggerate the claims of science comes mainly from the smaller fry, very rarely from the great. Furthermore, it is a basic feature of any mature university system that the undergraduates go far to educate themselves rather than to be educated. Is it, therefore, not too much to ask that they show a modicum of mental independence and discernment? But a heavy responsibility rests upon authority to refrain from misleading, if ever, in fact, it is tempted to do so.

Some sixty years ago, the philosopher Dilthey approached this subject in a different way. He considered that whereas direct observation is the natural method for the physical sciences, the social group needs vital experience or a "living through" for its proper functioning. Dr. Lindsay adds that to starve ourselves of this re-creative imagination in an industrial age is to invite disaster.

Towards the end of the course comes much valuable meditation upon psychiatry and the interrelations between the healer and the healed. It is clear that this is a matter of the very greatest delicacy, far exceeding that of ordinary medical practice in curing bodily ills. The risks, obviously, are the gaining of power over the individual's life, and the twin evil of reducing people to neat preconceived psychological categories. The survival of human personality, in contradistinction to the rough-and-ready good of the race, needs constant vigilance. We have moved a long way from Arnold's Victorian view of the meaning of religion as "morality touched by emotion".

The Master of Balliol has deserved well of his audience—and now of his readers too—in unfolding before them what amounts in effect to a confession of faith. It may not be possible, or even desirable, to agree in detail with all that these lectures involve, but of their weight, charm and generosity there can be no doubt. F. IAN G. RAWLINS.

VITAMINS AND HORMONES

Vitamins and Hormones

Advances in Research and Applications. Edited by Prof. Robert S. Harris and Prof. Kenneth V. Thimann. Vol. 1. Pp. xvii+452. (New York: The Academic Press, Inc., 1943.) 6.50 dollars.

IN 1938 and 1939 the first two volumes of "Ergebnisse der Vitamin- und Hormonforschung" were published in Leipzig by the Akademische Verlagsgesellschaft M.B.H. It is not known whether further volumes were published, but none seems to have reached Great Britain. In 1943 the first volume of "Vitamins and Hormones: Advances in Research and Application" was published by the Academic Press, Inc., of New York. The format of the new publication, which is edited by Prof. R. S. Harris of the Massachusetts Institute of Technology and Prof. K. V. Thimann of Harvard, is highly reminiscent of that of the Leipzig publication. The scope and objects of the new publication also appear to be similar. This similarity is clearly not accidental, and suggests that "Vitamins and Hormones" has some kind of continuity with the German publication.

The format of "Vitamins and Hormones" leaves nothing to be desired, style, paper and print being excellent. One editorial improvement can, however, be suggested: I wish that the bibliographies, in which the references are numbered, were all in alphabetical order; in several instances the references are numbered in order of appearance in the text. The numbering of references permits of the omission of authors' names from the text, but it is good to note that for the most part this has not been done in the present volume of "Vitamins and Hormones". Admittedly, space is thereby saved, but the inclusion of authors' names adds greatly to the interest of the text and often gives the reader immediate valuable guidance as to the quality and orientation of the work in question.

Comparison of the subject-matter of the present volume with the second of the Leipzig "Ergebnisse" gives an interesting idea of the progress of the subjects in four years. In the 1939 volume there were eleven reviews, of which four were devoted to hormones or related substances. In the 1943 volume there are ten reviews, of which only two are endocrinological. The earlier reviews had a more general biological flavour; the later ones are concerned chiefly with specific physical, chemical or biological problems. The review by N. Jolliffe and R. M. Most, on "The Appraisal of Nutritional Status", is especially valuable at the present time, and the article by T. Reichstein and C. W. Shoppee, on "The Hormones of the Adrenal Cortex", makes most interesting reading in comparison with Reichstein's review covering similar ground in the 1938 volume. Another article in the present volume which attracts attention is by R. P. Hall, on "Growth Factors for Protozoa".

A hearty welcome should be given to "Vitamins and Hormones". The ever-increasing flood of original papers and the progressive specialization of knowledge is steadily adding to the value of authoritative surveys. Unfortunately, the organization of the writing and publication of reviews has largely grown up haphazard, and it may be suggested that serious attention should be given to the problem of organizing reviews in a manner appropriate to their importance. At present, such surveys fall roughly into two categories according to the breadth and depth of the subject-matter. On one hand, there is the kind which appears in the review journals and in the "Ergebnisse" and similar publications, and now in "Vitamins and Hormones". Such a review tends to present a general picture of relevant information on a small self-contained subject, perhaps emphasizing very recent work, but none the less presenting the survey in historical perspective and in due proportion. Many of these reviews are of the greatest value and, except on subjects showing very rapid growth, need be repeated on the same subject only at fairly infrequent intervals. The increase of knowledge is constantly making necessary the subdivision of subjects suitable for treatment in a review of this type. The second kind of review deals only with very recent work and can cover a wide field, but successive ones dealing with the same subject must be produced at short intervals of one, two, or three years. Many who have tried to write a review of this type will agree that it is most difficult to give a coherent, consecutive and accurate account of one or two years' work in a subject. The inevitable gaps and the absence of background make it impossible to fit the new observations into the general framework of the subject and lead to an appearance of extreme superficiality. When the subject chosen is too wide for discussion even of the very recent work, other difficulties arise. Recently I had occasion to pay considerable attention to a review of this kind. In twenty-five pages of text (about one thousand lines) there were references to nearly five hundred papers, that is, nearly one to every two lines. A review of this kind can be no more than a breathless catalogue giving, in most instances, no real indication of the results obtained, but merely hurried comments on what the author or the reviewer believes the results to show. This technique is to be regretted, since the results themselves are often of more permanent value than the interpretations currently placed on them, and are therefore the more worth emphasizing. A. S. PARKES.

WORLD STUDENT RELIEF

THE WORK OF INTERNATIONAL STUDENT SERVICE

By JAMES L. HENDERSON

British Committee, International Student Service

INTERNATIONAL STUDENT SERVICE dates from 1920, when European student relief was brought into being as an autonomous section of the World's Student Christian Federation to cope with the vast problems of student relief and rehabilitation in the university centres of Europe. In 1926, when the purely relief problem was less acute, and the need for a permanent organization on an international basis had come to be felt by many thousands of students, it was necessary to give European student relief a legal status in Swiss law. To this end International Student Service was formed, an autonomous body continuing the traditional work of student relief and cultural co-operation on a basis of entire impartiality in all matters of religion and politics, and thus encouraging the participation in the work of all men of goodwill, whatever their race, nationality or belief*.

In the period between the first and second world wars, International Student Service performed a two-fold function. It continued its various student relief activities and it also linked them to constant and searching inquiries into the real nature of a university and the place of the student in society. The problems of student self-help and co-operation were discussed at various international study conferences, and documents were collected concerning methods of selection of gifted students, student loan-funds, health services, hostel administration, and the place of foreign guest students in the national universities. It became a department of university research, which benefited from grants from the Rockefeller Foundation, and the Carnegie Endowment for Peace, published a series of studies on the trends of higher education in the various countries and inquired into the problems of academic overcrowding and unemployment in the learned professions, and academic freedom. Official recognition of the pioneer work of International Student Service in this field was given when the League's Committee on Intellectual Co-operation adopted the survey as a basis for its own work (Walter M. Kotschnig, "Unemployment in the Learned Professions", Oxford University Press, 1937).

In 1939 the coming need for renewed large-scale relief was evident. The World's Student Christian Federation and Pax Romana approached International Student Service, and an agreement was drawn up which, while leaving all three organizations in existence, founded a new organization in which they were combined. For this new organization the old name of European Student Relief was revived, and offices in Geneva were staffed by men and women who had worked for years with International Student Service, knew the various countries, and had the confidence of university people everywhere. Since the outbreak of the present War, student relief work has fallen into three main categories: student prisoners-of-war of all nationalities, student refugees and internees, and those students, particularly in Greece and Belgium, suffering from the extremes of malnutrition. So far as the much-needed relief work on the Continent is concerned, the British Committee of International Student Service works largely through its international headquarters in Geneva and is financially dependent on the support it receives from university men and women, graduate and undergraduate alike.

The past twelve months have seen a further aggravation of the university crisis in Europe, as well as in other parts of the world. Everywhere the impact of war has increasingly marked academic life, the very continuity of which is and will be threatened during the coming months.

In the occupied countries of Europe the struggle of the universities has reached its climax following the measures taken early in 1943 by the German authorities for the total mobilization of all man-power available on the Continent. These measures have not spared the students. In Belgium, in Holland, in Norway, labour service has been declared compulsory for them, those refusing to register being excluded from the university. In Holland things have gone a step further: following several incidents for which student groups were held responsible, each student was required to sign a declaration by which he pledged himself to undertake no action directed against the occupying power. Here, too, those refusing to sign were excluded from higher learning. In France, the entire younger university generation has been mobilized for work in Germany, this measure being carried out by the French Government itself. Events in Norway are too vivid and recent to need further comment.

In all these countries, which have furthermore been afflicted by hard material privations, the students have made a brave stand. Few have yielded without resistance. In many universities strikes and other manifestations have taken place, expressing the opposition against the measures which have been imposed. Hundreds of students have even preferred to abandon their universities, to hide in their own country, or even fly abroad, with all the risks entailed, rather than be engaged against their will in the war machinery.

In belligerent countries also the situation of the universities has deteriorated during recent months. Not only has the number of students been drastically reduced, following mobilization from the age of eighteen or even seventeen; not only have many courses been shortened, with the object of adapting the curriculum to the war emergency; but also the very existence of the universities, as independent institutions devoted to the search for truth, has been questioned in some official quarters. In both belligerent parties voices have been heard which expressed the wish that for the duration of the War the universities should limit their aim to providing the State with an adequate number of technicians and young scientific workers required for the conduct of the War. Fortunately, however, this attitude has not been generally accepted, and leading university people have expressed themselves against a tendency which has found an expression in the emphasis laid everywhere on courses in natural and technical sciences as against arts and law. But the fundamental trend remains, and it is certain that, while the War will progressively drain all resources and energies in the belligerent countries, it will reduce the area in which cultural life will be able to develop with the freedom required.

While the universities in belligerent, as well as in occupied, countries have lost the greatest part of the younger generation who, in normal circumstances,

* International Student Service (British Committee), 11D (Lower) Regent Street, London, S.W.1.

would have filled their class-rooms, the number has increased again of the students who, cut off from their Alma Mater and forced for one reason or another to interrupt the course of their higher education, have faced alone and prematurely the gruesome hardships of the world at war; student refugees, for whom the summer months of 1943 brought new agony and who in hundreds had to fly from countries where they were threatened with arrest and deportation; students under the occupation, constantly in danger and weakened by months of nervous strain; student prisoners worn out by more than three years behind barbed wire; thousands and thousands of young men and girls who, in soul and body, have desperately suffered during the past year as a consequence of the present tragedy.

This development in Europe could not be watched passively by the European Student Relief Fund without an attempt being made to expand the work to some, at least, of the areas where the need was deepest and where, up to this date, conditions have prevented the organization of student relief.

Educational help to war prisoners and individual relief to internees or refugees in countries such as Switzerland and southern France—still under Vichy rule—was no more enough. Hunger was the major problem of thousands of students in occupied countries; an attempt to help them had to be made.

The delicate questions of principle connected with this broadening of the European Student Relief Fund programme were discussed by its executive on a concrete issue when, in the spring of 1942, an appeal was received through the International Red Cross for the students in Greece. At first the members of the executive felt uncertain whether a positive reply should be given to this call. The fear was expressed that the fact of the European Student Relief Fund engaging in a food relief scheme, in an occupied country, would create difficulties for its Anglo-Saxon friends, and perhaps make it impossible for them to obtain any longer the licences required for transmitting their funds to Geneva. However, after a full discussion, the executive finally agreed that the European Student Relief Fund should be ready to take its share in relieving the material needs of the student, as well as the intellectual ones. In order to prevent this decision from creating any difficulty for the committees in Allied countries, the following lines of policy were adopted:

(a) For all questions concerning relief in Greece, the European Student Relief Fund would use the channel of the Joint Relief Commission of the International Red Cross, the agency recognized by all Governments for the administration of relief in occupied countries, and which can guarantee, through its delegates on the spot, the rapid and impartial distribution of the resources made available.

(b) For the financing of food relief projects, only funds raised in neutral countries such as Switzerland, Sweden or Portugal, would be used, the resources received from the Anglo-Saxon countries being restricted to the financing of the work among prisoners of war, and in unoccupied countries. At the same time, the Committees in England and the United States should be invited to take part in the expanded programme in so far as they would be able to obtain, through the suitable agencies, the transfer licences required.

Along these lines the European Student Relief Fund has developed, since the summer of 1942, an increasing activity among students in Greece and other countries affected by famine. In some instances, even the Committees in Anglo-Saxon countries have been able to make special contributions for these projects. Thus the decision taken was justified by events.

Adapting itself to the aggravated situation, the European Student Relief Fund pushed ahead energetically with an enlarged programme. Fighting against hunger and despair became the slogan under which Geneva faced its increased responsibility through the fourth year of the War.

The plight of the student groups with which the Fund is related in Europe has been equalled in other parts of the world. There are the students of the U.S.S.R., whose country has been invaded, whose institutions of higher learning have been destroyed (see NATURE of January 8, p. 49). Under the pressure of the invading forces, they have had to withdraw into the depths of their immense country. There, in the central provinces of the U.S.S.R., universities and schools have resumed their work. But conditions are precarious; the students have, in many cases, lost all their belongings; they are cut off from their families; they lack the primary necessities of life. Their need is great.

This development can be compared to the striking events which, since 1937, have taken place in China. Here, too, many universities which were situated in the coastal areas have been transferred to the interior, in regions scarcely touched by civilization. The Chinese Government and the university communities concerned, through the efforts of which this transfer has been rendered possible, have thus given splendid evidence of their faith in the value of higher learning as the foundation of a national culture. Through the six years of their gallant struggle, the Chinese students have been greatly encouraged by the uninterrupted help which they have received through the agency of International Student Service and the World Student Service Fund in New York. This help has been continued during recent months, and the students of China have become increasingly aware of the fact that their fight is the fight of all students in the world, united by a common creed of the value of truth, objectively searched for and passionately desired.

Thus the trend already visible last year towards the unification of relief efforts in the various parts of the world has been reinforced. It is no longer possible to draw a strict line between the activities in and outside the realm of the European Student Relief Fund competence. The continental frame set up three years ago has been broken by the reality of war. There is one single world conflict. Only a united world relief administration will be able to cope adequately with the needs arising everywhere.

World Student Relief is now formally constituted. Its work will be conducted in the same spirit as that of the European Student Relief Fund, and its administration will likewise be entrusted to International Student Service. The headquarters of World Student Relief will be in Geneva, where the main executive, on which the member organizations will be adequately represented, will meet. In Europe the work will be continued under the auspices of the European Student Relief Fund. Two affiliated Committees are in process of formation: the first, in New York, which will be competent to handle relief problems on the American continent, in the Far East, and provisionally in the U.S.S.R., with which contact is impossible from Geneva; the second, in London, with the special responsibilities of organizing relief within the British Commonwealth, and of

co-operating with the New York Committee in the conduct of the Chinese action.

This arrangement should enable the groups concerned with student work to cover efficiently all five continents, provision being made for ensuring the continued development of relief activities in case one of the regional centres should be paralysed following an unexpected turn in the War. Thus, an organization now exists which is well equipped for serving the cause of student solidarity, in the East as in the West, during and after the War.

NATIONAL FLOUR AND BREAD

FOURTH REPORT

From the Scientific Adviser's Division, Ministry of Food

THE present report is a continuation of the work described in the previous three reports[1] on flour and bread in Britain, and deals with 440 samples of breadmaking flour and 1,408 loaves received in the period May 8–December 31, 1943.

Quality of Flour

The quality of British-grown wheat used in the grist depends upon the stock position, but it is now generally high, as the following table shows. For the bulk of the year 10 per cent of diluents (mainly barley, but also rye and oats) were also added.

BREADMAKING GRISTS IN ENGLAND AND WALES

Period	Home Grown Wheat (min. proportions)	Diluents (fixed proportion)	Imported White Flour (fixed proportion)
From 1. 1.43	35–45 per cent	5 per cent	5 per cent
25. 1.43	35–45	10	5
7. 2.43	35–45	10	5
19. 4.43	40–45	10	5
14. 6.43	30–40	10	5
21. 6.43	20–30	10	5
28. 6.43	20	10	5
6. 7.43	Optional, according to supplies available	10	5
23. 8.43	Some areas 25 per cent Others optional	10	5
30 8.43	20–35	10	5
13. 9.43	30–40	10	5
27. 9.43	45–50	10	5
4 10.43	50	10	From 24.10.43:7½
22.11.43	52½	7½	7½
6.12.43	55	5	From 12.12 43.10
20.12.43	57½	2½	10

In the earlier months of the year, most of the flour used in Great Britain was enriched with calcium carbonate at the rate of 7 oz. per sack of 280 lb. (0·16 per cent), and, in fact, by August 1, *all* the mills in the country had the necessary equipment to make this addition, which is now general.

Fibre and Vitamin B_1. The following table shows the different levels over the 440 samples. A correction has been made in the fibre figures to allow for the small percentage of added Canadian G.R. flour (white flour fortified with vitamin B_1 to about the same level of National flour).

The 'national average' figures for fibre and vitamin B_1 in the period under review were 0·55 per cent and 1·0 I.U./gm., or practically identical with the figures for the previous period, October–May 8, 1943 (cf. Third Report).

Protein Content. This depends on the percentages of Manitoba and English wheats, for which the average protein contents are about 14·0 and 9·4 per cent respectively. The protein contents of the samples received during each of the five months August–December averaged 12·25, 12·1, 11·1, 11·1 and 11·0 respectively.

Fibre		Vitamin B_1	
Value (per cent)	Samples (per cent)	I.U /gm.	Samples (per cent)
0 4 and less	4 6	1 20 and more	2 3
0·4 ,, ,,	31·6	1 10 ,, ,,	10 7
0 55 ,, ,,	52 6	1 05 ,, ,,	22·0
0·6 ,, ,,	67·0	1·00 ,, ,,	49·0
0·7 ,, ,,	87·2	0·90 ,, ,,	83·5
0·8 ,, ,,	94·7	0 80 ,, ,,	98 0
0 9 ,, ,,	97 2		

Granularity. The size of the bran particles continues to diminish, and 420 samples examined (after correcting for the added white flour) gave the following results:

Total over 5 silk (aperture 0·27 mm.)	Total over 8 silk (aperture 0·19 mm.)
1·5 per cent	5·4 per cent

Calcium Carbonate Content. One half-pound sample of flour from each mill is examined weekly to test the uniformity of the calcium carbonate additions[2,3]. The following table shows the results of these analyses for the month of November:

Calcium carbonate (oz /sack)	Corresponding capacity of mills (sacks/hour)	Percentage of total sack capacity examined
4·5 and less	238	4 4
4·6–5 5	448	8 1
5·6–6·4	1,156	20·9
6·5–7·5	2,599	47·0
7·6–8·5	745	13·5
8·6–9 5	290	5 2
9 6 and over	56	1·0

No. of samples tested = 1,310.

The calcium carbonate for the flour as a whole will be 7 oz. almost exactly; but there will be slight departures from this figure up and down the sack, depending upon the accuracy of feeding the calcium carbonate. Creta præparata is one of the most difficult products to feed because of its poor flowing properties, and the above table illustrates the range of variation due to this cause.

Quality of Bread

The following is a summary of the 1,408 loaves examined:

Quality	No. of loaves	Percentage
Good	297	21
Fair-Good	418	30
Fair	477	34
Poor	216	15

The lower general level of quality is due mainly to the high percentage of English wheat and the presence of diluent grains with grist. At the same time, it is of interest to note that all samples of flour received for analysis are also tested for baking quality under standard conditions. The 440 samples of flour gave the following results[4]:

Quality	No. of loaves	Percentage
Good	194	44
Fair-Good	115	26
Fair	100	23
Poor	31	7

The above results show that approximately 70 per cent of the loaves baked in the laboratory were

graded good or fair–good, whereas the corresponding figure for the commercial loaves was 51 per cent. This difference is a rough measure of the lower average result obtained in commercial as against laboratory production.

The following factors should be borne in mind, however : (*a*) The commercial bread had been posted from different parts of the country before examination. (*b*) The laboratory loaves were baked under controlled conditions of water absorption, fermentation and temperature. Such conditions are not always possible in commercial practice. (*c*) Particular loaves may have characteristics to suit local tastes, for example, thick crust, which may be regarded as faults in examination.

It is clear, therefore, that considering present conditions and the nature of the grist, the quality of much commercial bread is surprisingly good.

The faults in the commercial loaves were due to a number of factors, chief of which was incorrect fermentation of the dough ; but there was also evidence of wrong water absorption, poor manipulation and insufficient baking.

The work of this report was carried out at the Cereals Research Station of the Ministry of Food, St. Albans.

A NEW FORM OF MICROFILM READER

By DR. E. H. J. SCHUSTER

MICROFILM readers are divided primarily into two classes : in one, the magnified image of the film is projected on to a ground-glass screen from behind and is viewed as a transparency ; in the other, the image is thrown downwards on to an opaque screen. The first lends itself to the construction of a neater and more compact type of apparatus, but the second was thought to show a better defined image and one more pleasant to read. It was therefore chosen for an instrument designed for the Library of the National Institute for Medical Research. This consists of an open-fronted box, of which the bottom forms a reading desk and the top supports the projector. The sides are attached to a horizontal base-board ; they extend below the reading desk and are so shaped that the latter makes an angle of 20° with the horizontal, and the back slopes forward at the same angle to the vertical ; the angle of slope of the front edges of the sides is slightly less.

The Projector is an independent unit consisting of a 'Bakelite' platform on the upper surface of which are mounted the following components : (1) The lamp (a Kodak miniature projection lamp, 100 volts, 100 watts) in its housing. (2) The condensing lenses. (3) The pressure plates. One of these is fixed to the lens holder and the other is held in guides which allow it a limited movement backwards and forwards. Normally it is held against the fixed plate by springs at either end, but two small electromagnets, one mounted near each spring, when energized can overcome the resistance of the springs and separate the plates, giving a free passage for the film. (4) The lens holder, which as just stated carries the fixed-pressure plate at one end ; at the other is a focusing mount for the lens. The lens is of 2-in. focus and $f/3$ aperture. (5) The prism. The vertical face of this is as near as possible to the front of the lens, the oblique face is silvered and the centre of the horizontal face coincides with the axis of rotation of the projector platform. (6) The spool spindles. Mounted below the platform are its locating tube and the spool-spindle gearing. The locating tube is attached at right angles to the platform immediately below the prism ; a hole is cut in the platform concentric with it. The tube is about $2\frac{1}{8}$ in. in internal diameter and $2\frac{1}{2}$ in. long ; it slides into a cylindrical bearing which passes at right angles through the top of the box. The whole projector can be swung about this bearing through any angle, so that a page, however situated on the film, can be viewed with its top upwards. There is enough friction to maintain the projector firmly in any position. The outer circumference of the cylindrical bearing forms a journal for a ring gear, through which motion is transmitted from the control unit to the spool gearing.

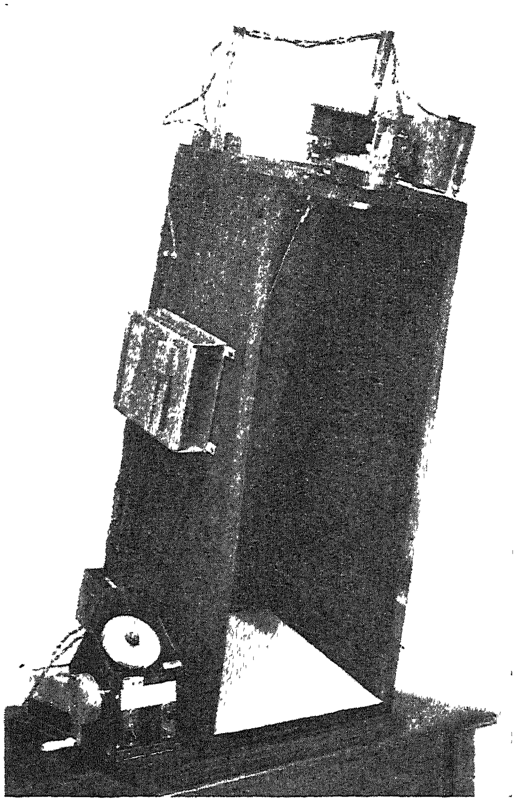

FIG. 1. MICROFILM READER AT THE NATIONAL INSTITUTE OF MEDICAL RESEARCH.

The Control Unit is attached to the left hand of the base board near the front, with its handle conveniently placed for operation by the left hand of the user. By this handle the film can be moved backwards or forwards, and it is so constructed that before the film can be moved the pressure plates must be separated.

Automatic Control of the Pressure Plates. This is effected in the following way : the handle has inner and outer concentric cylindrical portions ; the former is rigidly attached to the horizontal shaft of the control unit and the latter to a rod which passes centrally through the shaft and engages with the

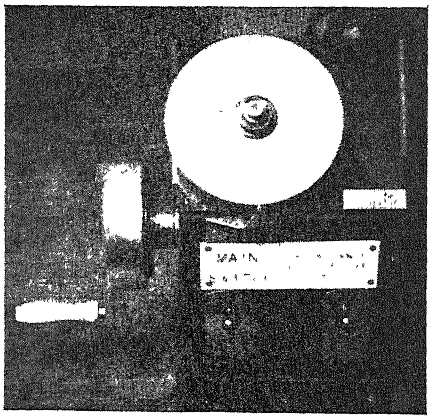

FIG. 2. CONTROL UNIT.

spring-loaded moving arm of an electrical key at its far end. When the handle is not in use, three equally spaced rollers with radial axes carried inside the outer handle cylinder rest at the bottom of three V-shaped grooves cut in the free edge of the inner handle cylinder. When the handle is turned, at first only the outer portion moves; the rollers ride up on one side or the other of their grooves, and this imparts a short axial movement to the outer handle, which causes the central rod to pull the moving arm of the key into contact with the fixed arm; an electric circuit is thus closed which energizes the magnets separating the pressure plates. When contact is made, further movement of the outer handle is stopped and the whole handle and the horizontal shaft turn as one piece. When the handle is no longer being turned, contact is broken by the spring, which at the same time pulls the rollers back to the bottoms of their grooves. A trickle charger supplies low-tension rectified current for the magnets.

Movement of the Film. Rotation of the handle is transmitted to the spools in the following way. On the horizontal shaft is mounted a spiral gear wheel which meshes with a similar wheel on a short vertical shaft in the control unit. A rod provided at each end with a universal joint is attached below to the vertical shaft just referred to, and, passing through a slot in the left side of the box, is attached above to another short vertical shaft. This passes through a bearing in the top of the box and carries above a spur wheel meshing with the lower edge of the ring gear; the upper edge of the latter engages with intermediate wheels, which in turn mesh with the spool-spindle gears.

The two spools may be differentiated as the fixed spool and the loose spool; the former is an integral part of the apparatus and the latter belongs to the particular film being read. The spindles carrying both pass through bushes in the projector platform and carry the spindle gears referred to above on their lower ends. The nature of the motion transmitted to the spindle gears is different in the two cases. When all gears are in mesh one revolution of the handle in either direction causes one revolution of the fixed spool in the corresponding direction, but the amount of rotation of the loose spool varies, being just that which is necessary to give off what film is being taken up by the fixed spool or to take up what is given off by it; this, of course, alters with the angle through which the fixed spool has been turned and with its diameter as affected by the amount of film wound on to it. When the fixed spool is full and the loose spool is empty, the latter will have to turn three times as fast as the former. The construction which enables the loose spool spindle to function correctly is as follows: its gearing is such that one turn of the control handle can cause three turns of the spindle, but by the interposition of a ratchet the turns will only be in the direction which will enable the loose spool to take up the film given off by the fixed spool; the giving off of film is permitted by the spindle slipping in the sleeve by which it is attached to its gearing. The correct degree of friction between the two is maintained by a spring-loaded felt washer. Slipping also occurs when the loose spool is taking up film, its degree varying with the relative amounts of film wound on the two spools.

The intermediate gears between the ring gear and the spool gears are mounted on swinging brackets; thus either spool can be thrown out of gear. It is convenient to use this device when inserting a film as it enables both spools to be turned as required by hand, and when rotating the projector. When rewinding a film on to the loose spool it saves a good deal of time and physical effort to throw the fixed spool out of gear; the loose spool then takes its time from its own gearing and a three-to-one increase of speed is obtained.

Indexing. As the films used in a library may be long enough to contain 800 pages of a book or more, it is of some importance to be able to wind straight to a point as near as possible to the page needed, without having to keep stopping the film to see where one has gone. If the tightness of winding does not vary very much, then whenever the film is used, any page on it will come into view each time after approximately the same number of degrees of rotation of the spool, or, which amounts to the same thing, of the handle. All that is required, then, is a measure of the rotation of the handle and the indexing of each film in relation to it. The first is provided by the control unit; its horizontal shaft carries a fine-pitch worm; this drives a wheel with a large number of teeth mounted on a shaft which passes through a bush in the front panel of the control unit. A dial graduated according to an arbitrary scale is mounted on the shaft where it emerges from the bush, being held friction-tight by a spring washer against a flange. Any division on the scale can thus be set by hand to a fixed reference point; but the friction is great enough to ensure that the dial will otherwise always turn with the shaft. The face of the dial is tilted upwards so as to be easily read by the user.

The index should be made when the film is first delivered to the library. The indexer turns the film to the first reference to be entered and then sets the dial to zero. Then as he works through the film he notes the dial reading at which each other reference appears. A table of contents 'paged' according to the scale on the dial thus results, from which such alphabetical indexes as may be required can be derived. Where the film is of a continuously paged book, a concordance between the dial readings and the page numbers of the book may be used in conjunction with the index of the book itself. As it would be very inconvenient to turn to the index in the film, it must be consulted from a copy, possibly abbreviated.

It may well be found convenient in libraries to store short lengths of film by sticking them together into long continuous rolls; the identification number of the roll together with the dial reading recorded

in a card index would enable any item to be found quickly.

Acknowledgments. The optical system used in the instrument described was designed by Mr. J. Smiles, of the National Institute for Medical Research, and he also selected the components. I have to thank Mrs. Moholy, director of the Microfilm Service of the Association of Special Libraries and Information Bureaux, for much valuable information and help.

'MAGNETIC' CURRENT

By JAMES T. KENDALL

Research Department, Metropolitan-Vickers Electrical Co., Ltd.

THE account of Ehrenhaft's claim to have discovered a magnetic current, which appeared in the daily Press of January 17, is very brief and possibly inexact. However, it appeared to be so completely contrary to the fundamental conceptions of electricity and magnetism, that thoughtful readers must search their minds for other interpretations of the experimental phenomena he is reported to have observed. Accordingly we at once set up apparatus to repeat the experiments which the Press had described.

The soft iron pole-pieces of a powerful electromagnet were immersed in dilute hydrochloric acid. A fine stream of bubbles was given off at each pole, and when the magnetizing current was switched on, the streams of bubbles tended to be deflected into the space between the poles, which was 1·5 mm. wide. Some of the bubbles were deflected downwards, against their buoyancy. Close observation showed that the motion of the bubbles was apparently caused by the motion of the liquid as a whole. Small inequalities of concentration, which are shown up as refractive index striations, permit any motion of the liquid to be recognized. Under the influence of the magnetic field, a steady streaming of the liquid from the pole faces into the centre of the gap and the consequent setting up of rotary currents in the liquid were observed. The streams of bubbles were entrained and carried along with this movement, and their motion was mainly controlled by it.

Confirmation of this motion of the liquid was obtained by repeating the experiment with the pole-pieces covered with a film of paraffin wax, and immersed in a solution of ferrous chloride. Under these conditions no bubbles were formed and no movement of the liquid in the magnetic field took place. However, if water was slowly poured into the solution, thus providing a non-uniform concentration of ferrous chloride, movement of the liquid in the magnetic field did occur. If the addition of water was stopped, the motion gradually died away as the concentration of ferrous chloride regained uniformity.

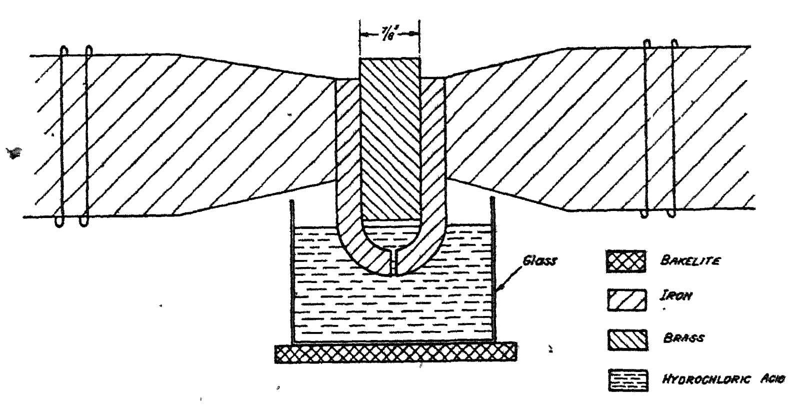
The movement of the liquid under the conditions above described can be explained very easily. It is due to the action of the strong, non-uniform magnetic field on the non-uniform concentration of paramagnetic ferrous ions. The parts of the liquid containing a high concentration of ferrous ions will tend to move into the strongest parts of the field. In confirmation of this, a number of other electrolytes were tried, both with waxed and unwaxed pole-pieces. No movement was observed with potassium chloride or cadmium sulphate under any conditions. Movement was observed with ferrous sulphate, ferric chloride and nickel sulphate under conditions of non-uniform concentration.

These experiments demonstrate conclusively that the general movement of the liquid, disclosed by refractive index striations, depends essentially on the presence of ferrous or other ions of high magnetic susceptibility. We wished to be sure that the movement of the bubbles formed at the unprotected iron pole-pieces was also due to the movement of the liquid, caused by the presence of the ferrous ions, which are provided by the solution of the pole-pieces in the acid. Accordingly the pole-pieces were heavily plated with cadmium and were then immersed in dilute hydrochloric acid. Bubbles of gas were liberated as before, but their motion in the liquid was entirely unaffected by the magnetic field: it was impossible to tell from their motion whether the magnetizing current was switched on or not.

In addition to the motion of the bubbles in the magnetic field, Ehrenhaft is also reported to have claimed that oxygen is evolved at the north pole and hydrogen at the south pole. Accordingly we immersed the bare iron pole-pieces in dilute hydrochloric acid and collected the gas from each pole separately. To facilitate this, a thin strip of mica was placed between the poles. The oxygen content of the gas was determined by heating a platinum filament to redness in it. A slight contraction in volume took place, corresponding to 0·54 and 0·49 per cent of oxygen in the gas from the north and south poles respectively. The probable error in analysis was $\pm$ 0·03 per cent of oxygen. This small percentage of oxygen was expected, since during the course of the experiment the pole-pieces became warm (due to the current in the magnetizing coils) and air dissolved in the acid would then be evolved. It would seem to be rather difficult to prevent the presence of a little oxygen (due to this cause) in the collected gas, and perhaps Ehrenhaft's reported observation may be accounted for in this way.

A third reported observation—that the pole strength of a permanent magnet decreases when immersed in dilute acid—we have not attempted to confirm. If sufficient of the permanent magnet were dissolved away, there would, of course, be a measurable decrease in its pole strength.

Our interpretation of the experiments we have made here may



EXPERIMENTAL ARRANGEMENT OF THE ELECTROMAGNET.

perhaps explain the effects attributed in the Press to Ehrenhaft. These may turn out to be no more valid than his previous claims of the existence of charges smaller than the electron (see *Phys. Z.*, 21, 675, 683; 1920). However, we must reserve final judgment until a fuller account of his experiments is available.

Apart from the failure here to confirm some of Ehrenhaft's reported effects, the observation of the movement of the liquid caused by paramagnetic ions in the magnetic field is of some interest. It may possibly form the basis of a method for separating the rare earth elements, the aqueous solutions of which differ markedly in magnetic susceptibility. The modern method of separating gaseous isotopes by thermal diffusion might be paralleled by a method of separating aqueous rare earth ions by 'magnetic diffusion'.

The accompanying diagram, drawn to scale, shows the arrangement of the magnet and soft iron pole-pieces: it should be noted that they are soldered to a brass block. This forms an important feature of the apparatus, and was provided to ensure that the experiments could not be vitiated by the passage of unsuspected leakage currents through the liquid. The average magnetic field between the pole-pieces was measured and found to be 11,000 gauss.

OBITUARIES

Prof. Pieter Zeeman, For.Mem.R.S.

PIETER ZEEMAN was born, the son of a clergyman, at Zonnemaire, Holland, on May 25, 1865. In 1885 he went to Leyden, where he became a pupil of H. A. Lorentz and Kamerlingh Onnes, and took his doctor's degree in 1893 with a thesis on measurements of Kerr's magneto-optical phenomenon. He held various positions in the physics department of the University of Leyden between 1890 and about 1900. In that year he was appointed professor of physics in the University of Amsterdam, where he spent the rest of his life.

It was while he was at Leyden, in 1896, that he discovered the effect since known by his name. In a nutshell, this is the fact, hitherto unknown, that the quality (frequency) of light is changed if the light is generated in a magnetic field. This implied an immediate connexion between two great branches of physical knowledge, light and magnetism, previously almost without contact. The mathematical expression of the fundamental effect in its simplest form is $\Delta\nu/H = \frac{1}{2}\, e/mc$, where $\Delta\nu$ is the change in frequency of the radiation, H the strength of the magnetic field, c the velocity of light *in vacuo*, and e and m the charge and mass of the emitting particle. Thus the change of frequency per unit field multiplied by twice the universal constant c is equal simply to the ratio of the charge to the mass of the emitting particles. This result, together with others of interest about the polarization and other details of the radiation, was deduced in 1897 by Lorentz as an inevitable consequence of the assumption that the emission of light was caused by the motion of electrified particles in an electro-magnetic field. While this statement would have been hotly contested in 1896, it is difficult to appreciate now that there was then any reasonable alternative short of the miraculous creation of light.

These considerations—and they could well be amplified—suffice to establish the basic importance of Zeeman's discovery; but in other respects also it was one of the most remarkable discoveries in the history of physics. Historically, it claimed immediate attention as a conspicuous success where Faraday had been baffled half a century earlier. The epoch of its origin was singularly auspicious. In 1897, measurements of e/m for the carriers of the cathode rays by the magnetic deflexion method were published by J. J. Thomson in England and by Wiechert in Germany. Their results were identical within the experimental error with the value found by Zeeman for the particles emitting spectral lines. But all these values were 1,850 times as great as the value of e/m for the lightest charged particle, the hydrogen ion, recognized by electrochemistry. If electricity was essentially atomic, a conclusion almost forced by Faraday's laws of electrolysis, we were here dealing with an apparently ubiquitous particle having a mass m much less than that of the smallest accepted particle, the hydrogen atom. This was settled soon afterwards by direct measurements of e by J. J. Thomson, confirmed by Planck's calculation from the intensity of heat radiation, which showed that their charge was indeed the same as the charge on the hydrogen ion. Thus was the electron born.

Another remarkable, and also perhaps fortunate, circumstance attending Zeeman's great discovery was that it was made at a time when the experimental technique was good enough to reveal the essential foundations, but not good enough to disclose the complicated structures which subsequent technical refinements brought out. Had the discoverer been confronted with all this at the outset, he might have despaired of ever making any sense of it. However, these developments, in which Zeeman himself played a notable part, have proved very important in several directions, and particularly helpful in clarifying and extending the quantum theory.

The Nobel Prizes, which are awarded annually, commenced in 1901. In that year the prize for physics went to Roentgen for his discovery of X-rays. In 1902 this prize was divided between Lorentz and Zeeman for researches on the influence of magnetism on the phenomena of radiation. This is another illustration of the timeliness of the discovery and of the prompt appreciation of its importance.

Zeeman's was a life devoted to increasing and improving our knowledge and understanding of physical phenomena by experimental methods. Much of it was in the field of magneto-optics, in which he was successful so early, and the greater part of it has had some optical connexion. This is not the place to review this in detail, but there is one thing that must be said. It is all characterized by extreme thoroughness and bears the hall-mark of the master of the art of experimental discovery.

Zeeman was elected a foreign member of the Royal Society in 1921 and an honorary fellow of the Physical Society in 1929. He was also a foreign or corresponding member of many other of the world's learned societies and academies. His achievements were recognized by the Dutch Government in creating him a Knight of the Order of the Netherlands Lion and a Commander of the Order of Orange Nassau.

His seventieth birthday, May 25, 1935, was celebrated by the publication in his honour of a volume comprising fifty original papers contributed by friends and admirers representative of the world's leading physicists.

Zeeman had a quiet and peaceful disposition, but he was by no means unforceful. His manner and temperament inspired immediate confidence. He was

very genial and likable, and his loss will be mourned by many sincere friends. He died on October 9, 1943, after a short illness and is buried in the Kleverlaan Cemetery at Haarlem. He was a worthy member of that company of great men who have made Holland, despite its handicap of size and population, stand out among the nations in the history of scientific achievement.

OWEN W. RICHARDSON.

Mr. Edward A. Martin

MR. E. A. MARTIN died at the age of seventy-nine on December 14 at Brighton, where his father had been mayor before him. Mr. Martin was well known as a lecturer on geological subjects, some of which he published in book form. His "Sussex Geology and other Essays" (Archer and Co., London, 1932) includes a chapter on "Clayton Windmills and the Dew-Ponds", among which is mentioned the windmill illustrated in NATURE of February 27, 1932, from the great Chinese Encyclopedia of 750 volumes in the eighteenth century. His researches on dew-ponds appeared in papers for the British Association and Royal Geographical Society. Other essays appeared in the *South-Eastern Naturalist*, of which he was honorary editor from 1916 until 1924.

Mr. Martin was honorary general secretary of the South-Eastern Union of Scientific Societies during 1924–35. To readers of NATURE he will be best remembered as the author, under the initials E. A. M., of the annual reports of Congresses of the South-Eastern Union, many of which he organized personally as well as contributing papers. He edited a bibliography of Gilbert White's writings for the Selborne Society; the geology side of *Knowledge* and the *Journal of the Commons, Open Spaces and Footpaths Society*. He was actively associated with the Croydon Public Library, and while residing in that borough, served during the War of 1914–18 as a commander of the Metropolitan Special Constabulary. On resigning the secretaryship of the South-Eastern Union he became a vice-president of the Union. He retired to Brighton in 1935.

In 1887 Mr. Martin married a daughter of H. T. Carpenter, a Common Councillor of London and then a ward in Chancery. His widow and three children survive and a nephew, Henry Martin, is editor-in-chief of the London Press Association.

T. DANNREUTHER.

WE regret to announce the following deaths:

Major H. J. L. Beadnell, formerly of the Egyptian Geological Survey, on January 2, aged sixty-nine.

Dr. F. D. Chattaway, F.R.S., fellow of Queen's College, Oxford, and formerly a distinguished chemist, on January 26, aged eighty-three.

Sir John Bretland Farmer, F.R.S., emeritus professor of botany in the Imperial College of Science and Technology, on January 26, aged seventy-eight.

Dr. C. B. Kingston, president in 1938–39 of the Institution of Mining and Metallurgy, aged seventy-six.

Dr. H. A. Mess, reader in sociology in the University of London, on January 23, aged fifty-nine.

The Rev. Sir John O'Connell, vice-president of the Statistical and Social Enquiry Society of Ireland, on December 28, aged seventy-five.

Sir Kynaston Studd, Bart., O.B.E., president and honorary chairman of the Polytechnic, London, on January 14, aged eighty-five.

Sir Thomas Ward, C.I.E., M.V.O., formerly inspector-general of irrigation in India, on January 27, aged eighty.

NEWS and VIEWS

Functional Collaboration in Colonial Territories

IN the House of Lords on January 26, Lord Listowel asked what action is being taken by the Government to prepare for the organization of security, development and welfare services throughout the British Empire on a regional basis. Lord Cranborne, Secretary of State for Dominion Affairs, replied on behalf of the Government. He said that, while contentious constitutional questions should be put aside for the time being, they must be continually borne in mind. So far as regional international machinery is concerned, the idea is still sufficiently novel to arouse suspicion. Nevertheless, our limited experience of such collaboration in commissions composed of representatives of nations with colonial possessions in the areas concerned has been encouraging. This scheme of constructing machinery to link up certain territories for purposes where common action is desirable has for some time been used in the British Empire as, for example, in the East African Governors' Conference, and regional grouping in the West African Colonies. An example of its extension on an international scale is provided by the Anglo-Caribbean Commission, the working of which has been very satisfactory. The essential point in considering such functional collaboration of neighbouring territories is the realization that it involves joint control, but not joint government. Referring particularly to the recent conference between Australia and New Zealand adumbrating a scheme for such an organization for the South Pacific, Lord Cranborne said that the Government welcomes this movement, and would also welcome the establishment of machinery of a collaborative and consultative nature in other areas in which various nations with colonial interests are concerned.

European Relief during 1919-20

THE Economic, Financial and Transit Department of the League of Nations, under the title "Europe's Overseas Needs 1919–20 and How they were Met", has issued an account of the failure to face the problem of Europe's post-war requirements of raw materials and essential manufactured goods in those years. The effects of that lack of policy were neither local nor transitory. The penury of European countries induced them to husband their resources by quantitative restrictions on exports and on imports, and the fear of their lowered standard of living induced others to refuse to accept their products. Commercial policy was driven from the very outset down the wrong road and never found another. In 1918 productive capacity in Continental Europe was at an extremely low level; in 1919 industrial production was about one half, agriculture one third, below normal. During 1919 and 1920 Continental

Europe imported about 17·5 billion dollars worth of goods from overseas, against an export of only 5 billions. Foodstuffs and finished goods formed an unusually large proportion of these imports; the imports of raw materials were relatively small. Northern and western Europe received proportionately much larger supplies than central and eastern Europe. The import surplus was met mainly from shipping services (1·8 billion dollars), emigrants' allowances (1·4 billions), expenditures in Continental Europe of the American and British armies (about 1 billion), yield on foreign securities (0·7 billion), inter-governmental loans (about 2·8 billion, of which 0·9 billion were relief loans), liquidation of security portfolios, and to the extent of roughly 2·5 billions from short-term credits.

Food was supplied by relief organizations, mainly during the first half of 1919, after which relief deliveries were on a much reduced scale. No international plan was evolved for the provision of the war areas with the other goods essential for the restoration of their economic life for nearly two years after the Armistice. The ter Meulen Plan, presented to the Brussels Conference in October 1920, for raw material credits, came too late and failed to materialize, and States were forced to acquire raw materials within the limits of their own financial capacities. The absence of provision for raw material credits was an essential factor in the process of currency depreciation, inflation and hyper-inflation. Inflation and currency depreciation in their turn caused a violent redistribution of national income and wealth, and prepared the ground for social unrest and political agitation. Action was only taken when inflation and the threat of social upheaval rendered it an unavoidable political necessity. This study gives a striking reminder of the magnitude of the disaster that resulted from the absence of any general plan, the failure of production and trade to revive, the social and political effects of inflation and the extent to which those effects were accentuated by the depression at the end of the first peace decade, and that depression accentuated by the burden of debt that Europe had assumed.

Canadian Seed Potato Eye Trade

By means of regulations issued in 1940, the Canadian Department of Agriculture exercises a strict control over the trade in seed potato eyes in the Dominion, where the raising of potato crops from eyes rather than from whole tubers is the usual practice in remote areas to which the transport of seed tubers is difficult. Eyes for sale must be cut only from certified seed, and their weight must be such that thirty-five eyes weigh not less than 1 lb. If the eyes are to be stored they are kept first for a week at 75° F. to encourage cork formation, but subsequent storage is at lower temperatures. Eyes intended for dispatch to growers soon after being cut have the cut surface either dusted with limestone or waxed to prevent drying out. The eyes must be free from obvious fungal, bacterial and insect damage and must be shipped in specified types of cartons, and with each batch of eyes sold a copy of the directions for planting issued by the Department of Agriculture must be sent. The directions for planting indicate the desirability of planting the eyes as soon as they are received in moist soil and with adequate protection against drying out. If planted in dry soil the eyes may fail to develop. The recently described experiments at Kew suggest that some of the precautions against drying out of the eyes may be unnecessary and that the use of controlled drying to produce 'dried potato eye chips' would further reduce the weight but not the viability of the eyes and so further simplify the difficulties of transport to remote areas.

Treatment of Cancer

The annual report for 1943 of the British Empire Cancer Campaign directed attention to recent developments in the treatment of cancer. In particular, reference was made to encouraging work on the inhibition of cancer of the mammary gland and of the liver by diets; and that it has been possible to confirm statements of workers in the United States and Canada, who claimed that the symptoms of cancer of the prostate are inhibited by the administration, in the simple form of pills given by the mouth, of diethylstilbœstrol, a synthetic substance resembling other glandular products. This is a very great advance; but we shall do well to remember that, although diethylstilbœstrol relieves the symptoms of this form of cancer and makes the patient once more a useful citizen, its effects are not yet uniformly successful and no surgeon has yet claimed to cure cancer in this way. The treatment applies, moreover, to only one form of cancer. These cautions do not minimize the greatness of the advance; they are necessary only because the public is acutely sensitive to any statements about cancer research, and insists that it must not be misled about a subject which only the expert can properly understand.

The public is right to insist upon this. It should remember, nevertheless, that cancer research is still a charity mainly dependent upon the gifts of public-spirited individuals. These benefactors, as well as the general public, have a right to be sure that the work made possible by their gifts is well co-ordinated and properly controlled, and that its results are passed on to the public through the proper channels. A recent announcement issued by the British Empire Cancer Campaign will help to reassure them about this. The Campaign intends to keep practising medical men informed about the progress of cancer research, so that the public may have, through them, the advice of the Campaign's experts about suggested cancer treatments. The Campaign also intends to do all that it can to promote investigation into methods of treatment of cancer and into theories of its causation, stipulating only that full disclosure shall be made of the nature and method of use of suggested treatment, and so on. To these conditions no reasonable man can object. They are, in essence, the conditions which any scientific worker imposes upon himself whatever the nature of his scientific work may be.

Malaria in the South-West Pacific

A new campaign to combat malaria in the South-West Pacific is to be financed under the Colonial Development and Welfare Act, 1940, and an initial grant of £65,000 to cover three years has been made for the purpose. The Anopheles mosquito, and consequently malaria, has hitherto been unknown in the territories of Fiji, Tonga, the Cook Islands, the Loyalty Islands, New Caledonia, the Gilbert and Ellice Islands and Samoa. In the islands to the west of Fiji, on the other hand, malaria is widely distributed. In peace-time, when there was little shipping traffic between the islands and air

services were unknown, the danger of the spread of infection was small, and the routine malaria control was considered sufficient. But since the outbreak of war, the establishment of large garrisons and the increase of air and sea traffic between the islands has greatly increased the danger of introducing malaria to the 'clean' islands. It is no longer safe to rely on quarantine measures; so steps are to be taken to eliminate possible places where Anopheles might breed.

Entomological surveys are to be made near shores and ports, and reconnaissance surveys of all potential breeding grounds. Normal anti-mosquito work will be intensified and danger places will be cleared, drained and oiled where necessary. At the same time an engineer will prepare a scheme for mosquito control on a long-term basis. The financial grant will cover the cost of plant, such as transport vehicles, garages, laboratories, equipment and tools, and the salaries of an engineer, surveyors, overseers, clerks, drivers and labourers for a period of three years. The measures to be taken will also wipe out the mosquitoes, other than Anopheles, already present in Fiji, which are carriers of such diseases as dengue fever and filariasis, and which would be a serious menace if yellow fever should ever be introduced to the territory.

Dehydrated Graphite Sols

DILUTE solutions of aqueous colloidal graphite have proved of service by their ready formation of electrically conductive, lubricative and opaque films (see NATURE, 149, 298; 1942). Bernard H. Porter, 25 South Street, Houlton, Maine, states that highly concentrated dispersions of the same colloid, compressed and dehydrated, constitute effective small-parts substitutes for metal. Irreversible in character, dehydrated masses of colloidal graphite are electrically conductive, markedly resistant to high temperatures, chemically inert, gas absorbent and easily machined. The commercial form of graphite hydrosol is slowly baked in pressure moulds at 90° C. Shrinkage may be so high as 85 per cent by volume. The resistivity of dehydrated graphite baked at 105° C. without pressure is 28·21 ohm-cm.; its porosity 24·93 per cent. Bars having greater conductivity than the graphite alone are formed by embedding strands of No. 30 copper wire, or strips of 60-mesh screen, in the graphite paste before baking. Metallic dusts may be admixed for the same purpose, though not without decreasing the tensile strength of the dried solid. Machine shaping, tapping and threading may follow as desired. Guard rings, connectors, electrodes, contacts, special-purpose forms and small parts normally made of metal are applications for dehydrated graphite sols.

Teletypewriter Test Sets

DISTORTIONS in teletypewriter signals are classified in three groups: bias, characteristic distortion, and fortuitous distortion. Bias, due to asymmetry in the circuit, causes all marking impulses to be lengthened or shortened. The increase or decrease is substantially equal in all the marking impulses, and the amount of bias is the lengthening or shortening expressed as a percentage of the unit pulse. As interpreted by a teletypewriter, the lengthening or shortening is what it would be if the bias affected only the beginnings of the marking impulses. Characteristic distortion differs from bias in that the amount of the distortion may vary from impulse to impulse and is dependent on the combination of the preceding impulses. Fortuitous distortion is normally non-repetitive and is caused by random interference such as cross-fire, lightning or power induction.

A teletypewriter test set has been developed by the Teletype Corporation (U.S.A.), which transmits code impulses corresponding to teletypewriter characters and distorts their timing relative to the start pulse by segments on two concentric rings over which conducting brushes are motor-driven at a constant speed. By adjusting the outer ring with respect to the inner one and connecting the segments of the two rings either in series or parallel, signals may be produced with any desired amount of marking or spacing bias, or marking or spacing end distortion. An article by W. Y. Lang (*Bell Lab. Rec.*, **21**, No. 12; August 1943) describes and illustrates the set.

Directory of Natural History Societies

A "Directory of Natural History Societies" in Great Britain and Ireland is now in course of preparation for publication by the Amateur Entomologists' Society in the near future. Its aim is to make known the existence and work of societies interested in any branch of natural history (except economic, agricultural or medical problems). The compilers wish to include as large a number of such organizations now existing in Great Britain and Ireland as can be brought to their notice, from national associations and regional unions to county, town, university or school societies. Names and addresses of as many organizations as possible, particularly of the smaller clubs and societies not affiliated to any naturalists' union, school or college organizations, and the like. are now needed, and the compilers will be glad of any help that readers can give. Postcards or letters should be addressed to Mr. W. G. Rawlings, 14 Westfield Park, Bath.

Merseyside Fauna and Flora

THERE is much that has more than a local interest in the recently issued Portfolio Vol. 2 of the Merseyside Naturalists' Association, covering mainly field work in 1942. From the botanical interest, J. D. Massey discusses in a lengthy paper the changes in the flora of the Liverpool area from 1838 to 1943, during which period fifty-nine plants have become extinct, forty-six native British species have become naturalized in the district, there have been seventy-eight naturalized alien incomers, while some 250 casuals have been recorded. The flora of this district is specially interesting from the influence of shipping introductions, of industrial slag heaps, building, drainage and pollution. Eric Hardy has a note, with photographs, of a large and well-established sycamore tree (*Acer pseudo-platanus*) growing entirely parasitically from a cleft in an alder tree (*Alnus glutinosa*) at Ince Blundell, South Lancashire. T. Edmondson has a survey of the avi-fauna of a mile-long colliery lake at Leigh with 109 birds, comprising forty residents, eleven summer visitors, fourteen passage migrants, twelve winter visitors and thirty-two occasional visitors, including such interesting species as gadwall. pintail, Bewick's swan, goosander, smew, bittern, red-necked phalarope; from the migration of waders and duck, it may be part of a route across the north of England. G. C. Miller has made some detailed and statistical studies of the nesting of the house sparrow, *Passer d. domesticus*, in which

he suggests that it is probable that three broods are reared when nesting begins early in April and only two when nesting is delayed by weather until May; the period between rearing one brood and commencing another averages ten days, making altogether 113 days or an average of four months devoted to the rearing of their young. There is confirmation of the observations of B. H. Ryves (*Brit. Birds*, August 1943), including retardation of egg-laying due to inclement weather. After the destruction of previous clutches the rapidity of egg-laying produced fresh eggs after intervals of only four or five days. An average of five young per pair is a normal seasonal increase. There are also interesting observations on the building of domed nests inside nest-boxes.

Powdery Mildew of the Rose

HORTICULTURAL beauty of the rose often depends as much on the foliage as upon the flowers. Powdery mildew caused by the fungus *Spaerotheca pannosa* is a very widespread trouble upon the leaves, particularly when roses are grown under glass. The disease can be minimized, but not controlled, by keeping temperature and humidity as low as possible for the growth of the plants. Mr. Wilbur D. McCellan has re-investigated the problem of control, chiefly by spraying methods (Cornell University Agricultural Experimental Station, Bull. 785. Ithaca, N.Y.; June 1942). Sulphur-containing sprays were found to be generally superior to those containing copper, though malachite green gave the best eradicant control. Good control without injury to foliage resulted from the use of particulate sulphur. Various wetting agents were also studied, and useful control was obtained by vaporizing sulphur at 112–115° C. A considerable reduction in the amount of mildew can be obtained by frequent syringing. The paper also includes descriptions of a method of measuring contact angles of spray drops, as a means of comparing their wetting power.

Mammalian Reproduction

THE title of a recent publication (1943) of the Imperial Bureau of Animal Breeding and Genetics fully indicates its contents. It is "Gestation Periods, a Table and Bibliography", compiled by J. H. Kenneth (Pp. 23. Edinburgh and London: Oliver and Boyd, 1943. 2*s*.). It contains a very long list of mammals with their common and scientific names, followed by the time in days of their gestation periods. The average time is given and also the minimum and maximum times where available. Where different times are given by different authorities, these are cited separately and all data are followed by references to the publications from which they are taken. In domestic mammals, separate times are given for the different breeds and in some instances for crosses between them. A number of workers will be grateful for this ready access to a scattered literature. A wide range of variation is shown from the sixteen days of the golden hamster, *Mesocricetus auratus*, up to the 426 days of the okapi, *Okapi johnstoni*, and 641 days of the elephant, *Elephas indicus*.

Health of Iceland

ACCORDING to the *Medical Officer* of November 13, the population of Iceland is now 121,579, of which 38,300 live in the capital, Reykjavik. The marriage-rate is 6·6, the death-rate 9·9 and infant mortality 35·9 per 1,000 live births. The chief causes of death are old age (1·6 per 1,000), closely followed by diseases of the heart and cancer, which both reach 1·3 per 1,000. Apoplexy, tuberculosis, pneumonia and accidents all rank about the same (0·8–0·9 per 1,000). Apart from influenza and pneumonia, infectious diseases are not important causes of death. Scarlet fever and erysipelas are of a much more virulent form than in Great Britain. 229 cases of tuberculosis were notified, of which 60 were non-pulmonary, and 104 cases were fatal. School medical inspection of children especially as regards tuberculosis is compulsory. Venereal disease is notifiable, and there has not been a diminution of cases during the last ten years. Occupation by foreign troops has been followed by more employment, more money, higher prices, longer working hours, housing difficulties, more accidents in factories and on roads and increase in immorality.

Typhus Fever in Bolivia

ACCORDING to the delegate of Bolivia at the eleventh Panamerican Sanitary Congress at Rio de Janeiro during September 7–15, 1942 (*Bol. Of. San. Panamer.*, 22, 590; 1943), typhus fever, which was formerly confused with typhoid fever, is an endemic disease which causes serious epidemics in Bolivia in the winter months. Its centre is the high Andean Plateau which has a million inhabitants, 90 per cent of whom are natives. The largest city affected is La Paz, which is in direct contact with the Indian population of the highlands as a trading, commercial and supply centre. The disease occurs only sporadically in the valleys, although they are inhabited by the same kind of natives as those on the plateau. During the Chaco campaign, when thousands of plateau natives were fighting among the rest of the inhabitants under lice-infested insanitary conditions, not a single case of epidemic typhus occurred, although in 1933 and 1935 the plateau was suffering from a great epidemic. During the last two years, cases of typhus have been uncommon and have been replaced by relapsing fever. The probable explanation of this is that the virus of the disease (*Rickettsia prowazeki*) is of a special type adapted to the Bolivian plateau and unable to flourish in a warmer climate, or that the lice in the valleys for some unknown reason do not transmit the disease.

Cerebrospinal Meningitis in War-time

ACCORDING to the July issue of the *Statistical Bulletin*, the organ of the Metropolitan Life Insurance Company of New York, cerebrospinal meningitis recorded its most extensive outbreak in the history of the United States in 1943: the number of cases up to the end of July was more than 13,000, and the total for the year will probably exceed 17,000 cases. Practically every part of the United States has been attacked, the State most affected being Rhode Island. Earlier, the disease was at an extremely low ebb, but in 1942 new cases began to increase in number. A large proportion of the cases reported in 1943 occurred in Army camps. England has probably suffered from cerebrospinal fever more than any other belligerent in this War, especially during 1940 and 1941, when the number of cases was nearly ten times the average for the three previous years. As the result, however, of the introduction of sulpha drugs in 1943, the majority of cases are now cured and the treatment of the disease has been revolu-

tionized. In the American Army camps, the death-rate has been only $3\frac{1}{2}$ per cent as compared with 34 per cent in the War of 1914–18; relapses have been virtually eliminated and the frequency of complications has been greatly reduced.

Training in Special Librarianship

THE very great increase in information services has created a demand for special librarians and information officers far in advance of the available supply of trained librarians. The Association of Special Libraries and Information Bureaux is therefore continuing to organize its emergency training in the technique of the special library by means of courses of twelve lectures given at weekly intervals, the first of which will start on February 16. Naturally such courses cannot pretend to give a complete training in librarianship; they are intended as first-aid help for inexperienced assistants in special libraries or information bureaux in place of the more thorough training not obtainable through war conditions. In the light of the experience gained in 1943, modifications have been made in the syllabus, which can be obtained on application to the General Secretary, ASLIB, 31 Museum Street, London, W.C.1. A fee of five guineas per student is charged for the course.

Clough Memorial Research Fund

THIS fund was instituted in 1935 for the purpose of encouraging geological research in Scotland and the north of England, the latter defined as comprising the counties of Northumberland, Cumberland, Durham, Westmorland and Yorkshire. A sum of approximately £30 is available annually. Applications for grants for the period April 1, 1944, to March 1945 are invited. Applications should state the nature of research to be undertaken, the amount of grant desired and the specific purpose for which it will be used, and whether any other grant-in-aid has been obtained or applied for. Applications must be in the hands of the Secretary, Clough Research Fund Committee, Edinburgh Geological Society, Synod Hall, Edinburgh, not later than March 1, 1944.

Recent Earthquakes

DURING September 1943, ten strong earthquakes were registered at the Dominion Observatory, Wellington, New Zealand. Epicentres have been determined at the Observatory as follow: September 6, near Macquarie Island; September 14, (1) near New Caledonia; (2) Samoa region; (3) region of 26° S., 175° W.; September 17, near Solomon Islands; and September 27, in the Kermedecs region. Sixteen other earthquakes and tremors were felt in New Zealand during the month. The strongest of these was Scale IV on the Modified Mercalli scale, and shocks with this intensity occurred on (1) September 3, in parts of Canterbury and Westland; (2) September 12 in Otira and near Arthur's Pass; and (3) September 28 at Eketahuna. Seismographs at Toledo in Spain registered twenty-two strong earthquakes during September 1943, the shocks of September 6, 10 and 14 being described as violent.

During the period Sept. 11–Nov. 26 inclusive, twenty strong earthquakes were registered at Kew Observatory. By far the largest ground vibration amplitudes at Kew were on Nov. 26, 1120 μ; Nov. 6, 590 μ; Oct. 23, 340 μ; and Nov. 3, 330 μ. The shock of Nov. 26 was in Turkey and has already been reported in NATURE (Dec. 11, p. 684). The shock of Nov. 6 was probably the one with epicentre just west of the island of Aroe Eilanden in the Banda Sea (lat. 5·5° S., long. 134° E.). The earthquake of October 23 probably had its epicentre 30 miles east-north-east of Sylhet in Assam, while that of November 3 probably originated 30 miles north-west of Susitna in Alaska. The last three mentioned epicentres were determined provisionally by the United States Coast and Geodetic Survey in co-operation with Science Service and the Jesuit Seismological Association on instrumental evidence. The next largest amplitudes during the period at Kew were Nov. 24, 105 μ; Oct. 24, 32 μ; Sept. 24, 28 μ; Oct. 22, 25 μ; Oct. 16, 21 μ; and Oct. 21, 17 μ. The last-named had its epicentre determined by the U.S. Coast and Geodetic Survey as being near lat. 16·5° S., long. 178° E., which is in the Pacific Ocean due north of the island of Vita Levu and due west of the island of Vanua Levu, both of the Fiji Islands group.

Announcements

THE Council of the Institute of Metals has elected four honorary members of the Institute, one each from the four principal Allied Nations: Her Excellency Madame Chiang Kai-Shek (China); Sir Lawrence Bragg (Great Britain); Dr. Irving Langmuir (United States of America); Prof. P. Kapitza (Union of Soviet Socialist Republics).

THE Astronomer Royal, Sir Harold Spencer Jones, will deliver the 1944 May Lecture of the Institute of Metals. He has chosen as his subject "Metals in the Stars".

THE Council of Newnham College, Cambridge, has awarded a Muriel Wheldale Onslow Prize for outstanding work in biology to Dr. A. B. Beakbane, of the East Malling Research Station.

PROF. J. MCLEAN THOMPSON will read a paper entitled "Towards a Physiological Interpretation of Modern Flowering", before the Linnean Society on February 10, at 2.30 p.m.

DR. PAUL HERGET, formerly assistant professor of astronomy at the University of Cincinnati, has been appointed director of Cincinnati Observatory in succession to the late Dr. Elliott Smith, and has been made professor and head of the Department of Astronomy in the University of Cincinnati. Dr. Herget, who is thirty-five years old, is an authority on celestial mechanics, having specialized on the computation of the orbits of minor planets and comets.

AT the annual meeting of the New York Academy of Sciences held on December 15, the following were elected to honorary life membership: Dr. O. T. Avery, of the Rockefeller Institute for Medical Research, New York; Prof. Alexander Fleming, professor of bacteriology, University of London (St. Mary's Hospital Medical School); Sir Frederick Gowland Hopkins, recently Sir William Dunn professor of biochemistry in the University of Cambridge; Dr. Alfred L. Kroeber, director of the Museum of Anthropology, University of California; Prof. The Svedberg, head of Physical Chemistry Institute, University of Uppsala; Prof. Arne Tiselius, professor of biochemistry, University of Uppsala.

LETTERS TO THE EDITORS

The Editors do not hold themselves responsible for opinions expressed by their correspondents. No notice is taken of anonymous communications.

Statistical Mechanics of Fields and the 'Apeiron'

In view of the difficulties encountered in the quantum theory of fields, we have developed a new approach to this subject which bears a much closer resemblance to ordinary quantum mechanics of particles than the existing theories (Heisenberg and Pauli). We consider the field in a finite volume Ω as a mechanical system described by its total energy and momentum. The latter are obtained from the classical expressions for the energy-momentum densities simply by multiplication with Ω. Each field component is considered as an operator (for the whole volume Ω) and is not regarded as a function of the co-ordinates at all. Between the field components we have established very simple commutation laws, analogous to the ordinary law $pq - qp = \hbar/i$, which depend on the transformation character of the field considered. For example, for the scalar meson field (potential v, its gradient f, its time derivative g; * means Hermitean adjoint; $[a, b]$ means $ab - ba$):

$$[v, g^*] = [v^*, g] = i\frac{\hbar c}{\Omega},$$

$$[g^*, f] = [f^*, g] = k\frac{\hbar c}{\Omega}.$$

Here the vector k is just an abbreviation for the commutators; it is a dynamical variable, but in virtue of the commutation laws a constant of motion, that is, it commutes with all field quantities, with the energy and the momentum.

We have verified[1] that in this case, and also for all other known fields, these commutation laws (or in the case of electrons similar anti-commutation laws) lead, with the transcription

$$[p_x, f] = \frac{\hbar}{i}\frac{\partial f}{\partial x}, \; [E, f] = -\frac{\hbar}{i}\frac{\partial f}{\partial t},$$

to the complete set of field equations and yield the same results as the usual quantization method (integral number of quanta with half-quantum zero energy).

But there appears a completely new feature of fundamental importance in the theory, connected with the vector k introduced above. It turns out that k corresponds to the geometrical variable 'wave vector' introduced by Fourier analysis in the usual theory. But it is here a real dynamical variable; its eigen values together with other quantum numbers define the pure states of the field. The distribution of these eigen values depends on the shape of the volume Ω, but can be assumed for a large volume to be uniform in the k_x, k_y, k_z-space (forming a cubic lattice).

In quantum mechanics it is necessary to introduce, apart from pure states, linear combinations of such, called mixtures; but it is not necessary that every possible state should appear in a mixture. (That is the main difference between our new theory and the usual one, because there each Fourier coefficient, considered as a q-number, necessarily appears, having at least its zero energy). A mixture contains in general a selection of k-points, each of which may still be occupied by any one of the quanta of the kind considered.

It is necessary to have a name for this sub-group of pure states belonging to the same k-value, which is something intermediate between the ordinary notion of a quantum (or particle) and a mechanical system. We suggest to use the word 'apeiron', introduced by the Greek philosopher Anaximander (about 550 B.C.) for the boundless and structureless primordial matter.

For a definite system (pure field) no mechanical knowledge is available to decide which apeiron may appear (which k-points are occupied by apeirons). Therefore we have to apply statistical methods. This is a new type of statistics, to be distinguished sharply from the ordinary distribution of quanta over the possible quantum states. For example, in the case of the scalar meson field referred to above, one has not only to assign the number of positive and negative mesons N_k^+, N_k^- (equal to 0, or 1, or 2, . . .) of a specified apeiron k, but also the number Δ_k (equal to 0 or 1) which indicates whether a place in the k-space is occupied by an apeiron or not. Both distributions must be made simultaneously; the N_k satisfy in this case the Bose-Einstein statistics (in the case of electrons the Fermi-Dirac statistics), while the n_k evidently always belong to the Fermi-Dirac type of statistics.

If, therefore, the total number of apeirons is a given number n, the distribution of $\bar{\Delta}_k$, the mean value of Δ_k, as a function in the k-space has the features well known from the electron theory of metals. For low temperatures all k-points are occupied up to a finite limit $|\,k\,| = k_m$, while all places with higher $|\,k\,|$ are empty. For higher temperatures this rectangular distribution curve becomes rounded off at the end, but in any event the function $\bar{\Delta}_k$ falls exponentially to zero for $|\,k\,| \to \infty$. If $\varepsilon_k\left(N_k^+, N_k^-\right)$ is the energy for the apeiron k in the occupation state N_k^+, N_k^- (for example, for the scalar meson field: $\varepsilon_k = \varepsilon_k{}^0\left(N_k^+ + N_k^- + 1\right)$) the total energy is $E = \sum_k \Delta_k \varepsilon_k$; it behaves as if the field were a Fermi-Dirac gas of molecules each of which was an apeiron and therefore had an infinity of states corresponding to the numbers N_k^+, N_k^- of quanta. If now Δ_k is replaced by its average $\bar{\Delta}_k$, the sum E will converge in spite of the zero energy $\varepsilon_k{}^0$ which is proportional to $|\,k\,|$.

It is to be expected that all divergent sums and integrals of the usual photon and meson theory are made convergent by the proper application of the apeiron statistics. In the case of collision phenomena, one has no thermal equilibrium; but the transition probabilities depend not only on the initial and final state but also on all possible 'intermediate' states. The cross-section integrals are extended over the statistical apeiron distribution.

The magnitude of the total number n of apeirons in thermal equilibrium has to be chosen in such a way that the self-energies of the elementary particles are correctly represented; that means that the upper limit k_m of the filled part of the k-space is connected with the radius r_0 of the electron by a relation of the kind $k_m r_0 \sim \hbar$.

The case of the electronic field can be treated in such a way that the contribution to the energy of each electron and positron is positive. But then there is a

negative zero energy, and therefore no thermal equilibrium of the apeiron is possible. This does not seem to us to be a real difficulty, because a set of electrons left to themselves is not in equilibrium. Electric clouds like those in metals exist only on account of the fact that in this case the interaction energy with other particles (which is omitted in our considerations) is large compared with the thermal energy.

Investigations on the application of this theory to the elementary particles, their masses and their mutual collision cross-sections are in progress.

Rate of *n*-fold Accidental Coincidences

THE rate of accidental coincidences between two Geiger counters is given by $R_2 = 2.N_1.N_2.t$, where N_1, N_2 are the rates of the two single counters and t is the resolving time of the recorder. This formula is sometimes generalized for n-fold coincidences as $R_n' = N_1.N_2 \ldots N_n.(2t)^{n-1}$. This formula is, however, incorrect and it should be replaced by

$$R_n = n.N_1.N_2 \ldots N_n.t^{n-1} + \text{terms in } t^n. \quad . \ (1)$$

As the formula for the rate of accidental coincidences is of practical interest, and I have not come across its derivation, a short explanation follows.

Consider a pulse of the counter 1 at the time 0. A necessary condition for this pulse to be recorded as an n-fold coincidence is that in the interval $\pm t$ each of the remaining $n - 1$ counters gives rise to at least one pulse. Neglecting all but the lowest power of t, the probability for this is

$$P = N_2.N_3 \ldots N_n.(2t)^{n-1} \quad . \ . \ . \ . \quad (2)$$

The pulse of the first counter, together with the $n - 1$ pulses of the other counters, only gives rise to a coincidence if the interval between any two of the pulses is less than t. The probability Q that $n - 1$ pulses of the counters $2, 3 \ldots n$ all inside the interval $\pm t$ are suitably arranged to give a coincidence is estimated as follows.

The $n - 1$ pulses may all be in the interval $0 - t$. The probability for this is

$$Q_1 = 2^{-(n-1)}.$$

In this case the pulses give rise to a coincidence.

Alternatively, the first pulse x of the group may be in the interval $-t', -t' + dt'$ and the remaining $n - 2$ pulses inside the interval $-t', -t' + t$. The probability for this is $(n-1)\ (dt'/2t)2^{-(n-2)}$; the pulses again give rise to a coincidence. The probability for a coincidence while some pulses are in the interval $-t$ to 0 is thus

$$Q_2 = \int_{-t}^{0} (n-1)2^{-(n-2)}\frac{dt'}{2t} = (n-1).2^{-(n-1)}.$$

The total probability is

$$Q = Q_1 + Q_2 = 2^{-(n-1)}.n \quad . \ . \ . \ . \ . \quad (3)$$

Thus the probability that $n - 1$ pulses fall into the interval $\pm t$, and that these pulses are suitably arranged to give a coincidence, is found from (2) and (3) as

$$P.Q = n.N_2.N_3 \ . \ . \ . \ N_n.t^{n-1}.$$

The above expression multiplied by N_1 gives equation 1.

Comparison of the Behaviour of Rubber-like Materials under Constant Stress and Constant Strain Conditions

MANY experimental data have been published substantiating the use of the Nutting equation,

$$\psi = S^{\beta}\sigma^{-1}t^{k},$$

where S is shear stress, σ is strain, β, k and ψ are constants, when a series of constant stress experiments is performed. Our own as yet unpublished results confirm the equation over an even wider range of materials.

For relaxation experiments, test pieces are given a definite strain as rapidly as possible, the resulting internal stress being then allowed to dissipate with no more change of strain than is required to operate a strong spring whose deflexions, which record the stress, can be read by optical magnification.

According to Maxwell's equation[1], the rate of stress dissipation should be proportional to stress itself, but many authors have shown that this is not so for most complex materials. Simha[2,3], notably, has discussed whole spectra of relaxing systems each of which is Maxwellian and has its characteristic relaxation time (t_r).

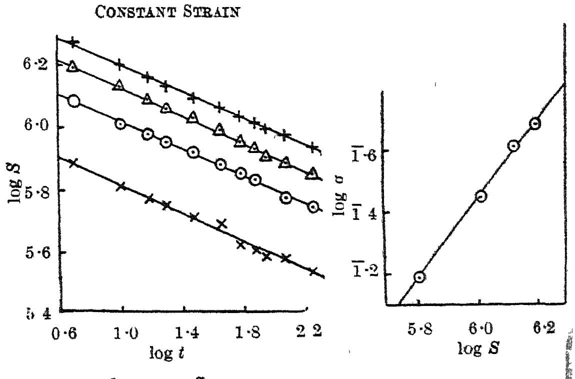
The appropriate fractional differentiation of Nutting's equation gives

$$\left(\frac{\partial S}{\partial t}\right)_{\sigma} = -\frac{k}{\beta}\frac{S}{t}.$$

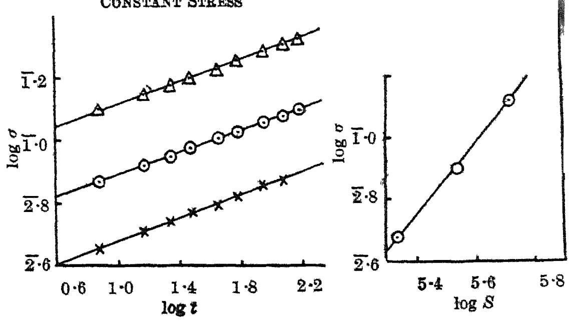
Maxwell himself suggested that in complex materials t_r might well be a function of S, and the above equation is perhaps the simplest expression of this suggestion, since t_r is proportional to a power of the stress.

We have investigated a number of rubbers and rubber-like materials in tension and a few in compression, and with the exception of some very soft materials, find little if any deviation from linearity when log S is plotted against log t for a series of

CONSTANT STRAIN



CONSTANT STRESS



constant strains. Such curvature as there may be suggests still further deviation from the Maxwell plot.

It is also interesting that the values of k, β and ψ (or $1/\zeta$, the volume of the $S : \sigma : t$ figure[4]) calculated from constant stress (compensating for the change in cross-section) and constant strain experiments are so nearly the same that differences can scarcely be much greater than experimental error. This is rather striking, since, as Scott Blair and Caffyn[5] have pointed out, in the former type of experiment k is determined from the continuous change of strain with time, whereas, in the latter, since the slope of the experimental curve is k/β, data from a series of different experiments have to be introduced. The curves deriving β are, naturally, less accurate in both experiments than are the 'continuous' curves.

This treatment seems to us to present a much simpler way of viewing the relaxation behaviour of complex materials than is the concept of a spectrum of Maxwellian components, but further data will be needed before the full extent of its applicability can be assessed.

The figure shows typical experimental curves. The derived curves, relating stress to strain for a defined time, are given on the right of the diagram.

Our thanks are due to the British Electrical and Allied Industries Research Association for a grant.

Ice-Crystal Haloes

BRAVAIS, in his great memoir[1] on this subject, divides circumzenithal arcs into two classes, ordinary and extraordinary. "Les arcs circumzenithaux ordinaires sont les arcs tangents aux halos de 22 degrés et de 46 degrés."

There are two arcs tangent to the halo of 46°, an upper and a lower. The upper is much the more frequent, and unquestionably the most brilliant of all those connected with haloes and parhelia. It encircles the zenith and always appears about 20°–25° from it. The colours are as brilliant as those of the rainbow, the red border being towards the sun and the blue border towards the zenith. It often appears unaccompanied by the halo of 46°.

According to Galle, the tangent arc to the halo of 46° is due to refraction of light through hexagonal prisms terminated by planes perpendicular to the hexagonal axis, the prisms being distributed and fixed with that axis vertical. The light enters obliquely at the upper basal face and comes out through the adjacent vertical face. Bravais showed that the effect of this arrangement would be to produce an arc concave toward the zenith when the altitude of the sun was less than 20°, and concave downward when the sun's altitude was greater than 20°. But such a reversal of curvature has never been observed, so Galle's explanation does not meet the case.

Bravais's own explanation of this arc is based on the very reasonable supposition that the crystals are not fixed, but oscillating or fluttering through a small angle about the vertical. The greater the amplitude of oscillation the more are the colours of the arc mixed together, and especially so when the sun's altitude is less than 16° or greater than 28°; but the red remains pure.

In order that the crystals may flutter about their hexagonal axis, one must suppose that they are of tabular habit; for as Wood has pointed out[2], Bravais was wrong in supposing that snow crystals are in the position of least resistance while falling.

The conclusions to be drawn from all this are that: (i) the common circumzenithal arc and the arc tangent to the halo of 46° are one and the same thing; (ii) the tangent arc of the 46° halo is not invariably accompanied by the halo itself; (iii) tabular hexagonal crystals fixed as in Savile's Fig. 1[3] give rise to Galle's arc. Precisely the same type of crystal, when fluttering, gives rise to the upper tangent arc to the 46° halo.

Hydrogen Content of the Sun and of Stars of Small Masses

THE simple Cowling model of a star of small mass with a convective core and radiative envelope is of considerable importance in view of Bethe's theory of energy generation, which demands a stellar model of the convective radiative type. It appears possible to use this simple model so as to conform to Bethe's formula of energy generation on one hand and furnish an approximate value of the hydrogen content of a star of small mass on the other. For formulæ relating to the Cowling model we shall refer to Chandrasekhar's "Introduction to the Study of Stellar Structure", pp. 351–54. The constant $\varkappa_0$ in Kramers' opacity formula will be taken as $3\cdot9 \times 10^{25}(1-x^2)/\bar{t}$, where $\bar{t}$ is the mean guillotine factor, and x the hydrogen content; helium content being assumed zero.

It may be noted that the substitution of the observed L, M, R of a star in the Cowling model formulæ may lead to a serious discrepancy with Bethe's energy generation formula. For example, in the case of the sun the substitution of L, M, R in the formula of the Cowling model (Chandrasekhar, *loc. cit.*, ix, 206, 208 and 209) would give for $\bar{t} = 5$ (Strömgren):

$$T_c = 21\cdot4 \times 10^6 \text{ K.}, \rho_c = 52\cdot3 \text{ gm./cm.}^3, \quad \mu = 1\cdot028, X \sim 0\cdot31.$$

But if the stellar equations of equilibrium be integrated *from the centre outwards* with these T_c, ρ_c values, and the luminosity calculated by Bethe's formula be used to determine the change to radiative gradient as usual, we shall arrive at an all-convective model—there will be no radiative envelope. This situation is expected to arise quite generally for this type of adjustment.

If μ, ρ_c and T_c be given, we can, on one hand, calculate the luminosity L_{Cow} by the Cowling model formula, and also another value of the luminosity L_{Beth} by integrating Bethe's formula from the ς, T values inside the core within which nearly the whole of the energy generation is found to take place. Suppose now only μ is assigned, and T_c and ς_c are

so chosen that $L_{\mathrm{Cow}} = L_{\mathrm{Beth}}$ = luminosity of the given star. From the Cowling model formulæ (Chandrasekhar, *loc. cit.*, ix, 208, 209), we can calculate M and R for the star, which may be compared with the observed values. The adjustment of the equality of the luminosities may be made thus. We obtain

$$L_{\mathrm{Beth}} = 4\pi\varepsilon_0\left(\frac{5k}{8\pi\mu GH}\right)^{3/2} T_c^{5/6}\rho_c^{1/2}\int_0^{\xi}\theta^{7/3}e^{-b/\theta^{1/3}}\xi^2\,d\xi$$

$$= A\rho_c^{1/2}\,I(\xi,T_c),$$

I representing the integral and $b = 56 \times (2\times 10^7/T_c)^{1/3}$. Also the Cowling model formula gives

$$L_{\mathrm{Cow}} = B/\rho_c^{5/2},\ B = 0{\cdot}1968 \times \frac{16\pi ac}{3K_0}\left(\frac{5k}{8\pi\mu GH}\right)^{1/2} T_c^{8}.$$

Equating the two values of L at the interface ξ_i of the convective core, we obtain for a definite T_c the corresponding density by

$$\rho_c^3 = \frac{B}{AI(\xi_i,T_c)}.$$

By trial, T_c may now be so adjusted that the calculated luminosities agree with the given luminosity of the star.

For the sun, taking $\mu = 1$, $X \sim 0{\cdot}35$, and $\bar{t} = 5$ (Strömgren), we obtain by such an adjustment (the luminosity neglected outside the core not exceeding 5 per cent, as shown by calculation)

$$T_c = 20{\cdot}3 \times 10^6\ \mathrm{K.},\ \rho_c = 43\ \mathrm{gm./cm.}^3,$$
$$M = 2{\cdot}1 \times 10^{33}\ \mathrm{gm.},\ R = 7{\cdot}6 \times 10^{10}\ \mathrm{cm.}$$

The agreement with the observed M and R is very close in this case. The integration from inside will give a convective-radiative model of the desired type. It appears that the best agreement of the Cowling model with Bethe's energy generation formula can probably be obtained in this manner. Further, it also opens up a possibility of approximately determining the hydrogen content (for zero helium content) of stars of small masses on the basis of the Cowling model by adjusting x in such a way that a fairly good agreement between the three observed and calculated stellar parameters is achieved by the above method. This, of course, tacitly assumes that the relative size and mass of the core of a star obeying Bethe's formula are approximately the same as those given by the Cowling model.

It would also appear that a solar model of the convective-radiative type in agreement with Bethe's energy generation formula should have a central temperature of about 20 million degrees (standard model), but the central density should be much lower than that suggested by the standard model.

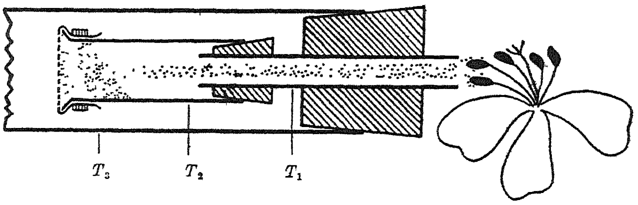
Collection of Pollen and Artificial Wind Pollination

THE collection of pollen for its immediate use or for storage is a common practice in plant breeding. No difficulties usually arise when the pollen is to be used at once, but if it is stored together with the anthers according to the usual technique, it is difficult to handle after the anthers have dried.

If pollen free from anthers is required, except in wind-pollinated plants, it is almost impossible to separate effectively the grains from the anthers by hand. Large amounts of clean *Oenothera organensis* pollen were needed for immunological experiments; but separation by hand was impossible because of the minute threads which connect the pollen grains in the Onagraceæ. This led us to devise a new method of pollen collecting based on air suction. A household vacuum cleaner with a suitable adaptor, shown in the figure, is extremely effective for collecting large or small quantities of pollen. The adaptor can be made from a piece of ¼-in. glass tube (T_1), and the top half of a 1-in. boiling tube cut into two (T_2). A piece of linen or other porous material is fixed with a rubber band around the flanged edge of the tube; a rubber bung, through which passes tube T_1, is pushed into the other end. The whole adaptor fits into the metal end of a vacuum extension tube (T_3). When the end of tube T_1 is placed near to the anthers of a flower, pollen is drawn in and trapped. By this simple device 1 gm. of clean pollen can be collected from fifty flowers of *Oenothera organensis* in less than four minutes, that is, 2·5 mgm. per anther.



After the pollen is collected it can be conveniently stored by removing the tube T_2 and corking the end. The best diameter of the collecting tube T_1 varies according to the type of flower. For Œnothera ¼ in. is suitable, but for radish half this diameter is better because with the large tube, petals are collected as well. For some flowers in which the anthers are well exposed, as in apples and cherries, a bell-mouthed tube can be used with the advantage of collecting from a cluster instead of individual flowers.

The device with the air current reversed can be used as a pollinator. A press-button valve releasing staccato puffs of air must be fitted between the fan and the pollen container. In this way a flower or a whole influorescence can be pollinated with one press of the button. An insect-pollinated flower is then wind-pollinated under controlled conditions. To regulate the amount of pollen delivered it can be diluted with a 'powder' such as Lycopodium spores or talcum; the degree of dilution varying with the type of flower. The method should greatly reduce the labour of mass pollination which is necessary in the breeding of fruit and forest trees in the temperate countries and in the breeding of dates, sugar-cane and bananas in the tropics. The increasing utilization of hybrid seed production in vegetables and fruit will also require mass pollination methods. Lack of adequate cross-pollination which may be due either to the planting of large blocks of one variety of fruit tree or to low insect activity has led occasionally to the use of hand collection and pollination in some 100-acre orchards[1]. If artificial pollination has to be resorted to on a big scale then the present method could be used with advantage. A similar method has been used on grape vines by spraying the flowers with a suspension of pollen in water[2].

Furthermore it will now be possible to measure

accurately and quickly the pollen production of plants, of which at present there is little knowledge. Such information is of biological interest in relation to the mating systems of plants. The pollen production of fruit tree varieties is of practical value in relation to insect activity and the efficiency of varieties as pollinators.

Leaf Lipids of Forage Grasses and Clovers

During the past five years, the lipids of forage grasses and clovers have been investigated in this laboratory. The results so far obtained have indicated the complexity of the lipids as well as the need for careful preservation and preparation of the samples.

The results of examination for lipid constituents of ten cocksfoot (*Dactylis glomerata*) samples collected at different periods may be summarized as follows:

	Total lipids	Lipids soluble in acetone at 0° C.: Total	Fatty acids	Unsaponifiable	Waxes	Phospholipids
Mean percentage on dry matter	6·12	5·06	3·13	0·96	0·86	0·20
Standard deviation	1·05	0·83	0·70	0·17	0·09	0·07

The fatty acids, comprising 2·15–4·03 per cent of the dry weight, were found by ester fractionation to have the following mean composition:

	Saturated: C_{14}	C_{16}	C_{18}	as C_{26}
Weight per cent	1·4	11·2	2·6	1·5

	Unsaturated: C_{14}	C_{16}	C_{18}
Weight per cent	0·4 (2·0 H)	6·4 (2·0 H)	76·5 (5·1 H)

Smith and Chibnall[1] deduced from bromination experiments that the unsaturated acids of cocksfoot consisted of approximately two thirds octadecadienoic acid and one third linolenic acid. In this work, however, the mean unsaturation of the C_{18} esters indicated approximately equal proportions of these two acids. In addition, dihydroxystearic acid (m.p. 131–132° and not depressed by admixture with authentic dihydroxystearic acid m.p. 132°) was prepared by oxidation of the acids from the C_{18} unsaturated methyl esters insoluble in acetone at −78° C., the yield corresponding to approximately 0·6 per cent oleic acid in the C_{18} unsaturated acids. By oxidation of a concentrate of C_{16} unsaturated acids, dihydroxypalmitic acid (m.p. 122–123°, m.p. 123–124° admixed with authentic dihydroxypalmitic acid m.p. 125°) was also prepared.

The low yield of phospholipids (0·1–0·3 per cent of the dry weight) found for cocksfoot (*Dactylis glomerata*) and for rye grass (*Lolium perenne*) preserved in cold alcohol or dried in a current of air at 35° or 70° C. is in agreement with the findings of previous workers[2]. Freshly-cut cocksfoot or rye-grass preserved by dropping into boiling alcohol contained, however, 1·5–1·7 per cent phospholipid. With boiling alcohol treatment the free fatty acid content of the lipids insoluble in acetone at 0° C., expressed as oleic acid, was 6–14 per cent as compared with the higher values of 30–37 per cent obtained by other treatments. In the case of white clover (*Trifolium repens*), similar high phospholipid values were obtained for samples preserved in boiling alcohol or dried in a current of air to 70° C.

The isolated phospholipids of cocksfoot, rye grass and clover contained usually *ca.* 2·0 per cent phosphorus. Relatively pure lecithin-cephalin fractions (P = 3·40 per cent, N = 1·4 per cent) amounting to 15 per cent of the total phospholipid were readily obtained. However, attempts to prepare pure lead phosphatidate, the crude preparations of which amounted to 10 per cent of the total phospholipid, were unsuccessful. Application of similar technique to rape phospholipids yielded without difficulty almost pure lead phosphatidate (P = 3·33 per cent, ash 32·5 per cent). The highest yields of the phospholipids were obtained by boiling the cold-acetone-insoluble lipids with ten volumes of acetone, cooling to 35° C. and decanting the waxes which remained in solution. The traces of phospholipid retained in the wax fraction were afterwards removed by crystallization from ether at − 20° C.

In general, the phospholipid fatty acid composition was found to resemble that of the corresponding glyceride, with the exception that the mean saturation of the C_{18} unsaturated acids tended to be lower (3·7–4·8 H) than in the case of the glycerides (5·0–5·3 H).

Acetate Utilization for Maintenance of Motility of Bull Spermatozoa

The oxidation of acetate by mammalian tissue *in vitro* has been demonstrated; but comparatively little is known concerning the pathway of its oxidation or the possibility of its oxidation being coupled with phosphorylation. Recently Barcroft, McAnally and Phillipson[1] showed that acetate maintained the beat of the perfused rabbit's heart. Their demonstration suggests the ability of acetate to furnish energy for the maintenance of function in this tissue.

In view of their results, it seemed desirable to present data which have been obtained on the utilization of acetate by spermatozoa. It has been shown that washed, ejaculated bull spermatozoa suspended in phosphate-saline maintain their motility by the oxidation of intracellular phospholipids[2]. The addition of other metabolites to such sperm suspensions results in no further increase in respiration. If, however, the oxidation of the lipid is inhibited by 2,4-dinitrophenol, the utilization of various added metabolites may be readily demonstrated[3]. With epididymal spermatozoa the endogenous respiration is low and the effect of added metabolites is immediately shown. The effect of acetate on respiration and motility of both epididymal and of ejaculated

spermatozoa treated with 2,4-dinitrophenol is shown in the accompanying table. For comparative purposes data for pyruvate are included for each type of spermatozoa listed in the table. Stimulation of respiration and prolongation of motility, by acetate, were obtained with certain collections of ejaculated spermatozoa by storing at room temperature until the intracellular reserves had been partially depleted. The utilization of acetate as well as of the intracellular lipid reserve[5] is completely inhibited by malonate. Evidence to be presented elsewhere indicates that the mechanism of lipid metabolism in the sperm follows a pathway similar to the *iso*citric acid cycle. Breusch[6] has recently claimed that citric acid is an intermediate in fat metabolism. The presence of an active aconitase in the enzyme preparations from spermatozoa produces an equilibrium of *iso*citric, *cis*-aconitic and citric acids and prevents the identifying of the primary condensation product. Acetate may enter such a cycle but the mechanism is as yet undetermined. It has been shown that acetate increases the respiration and supports motility of epididymal, and of 2,4-dinitrophenol-treated ejaculated spermatozoa of the bull. This work was supported by a grant from the National Committee on Maternal Health.

Effect of Factors Influencing Mutability

UNSTABLE genes are found to be very suitable for the study of many factors influencing mutability, because high-mutability stock yields significant results for a number of flies examined much lower than with standard *ClB* method. In this study the influence of chemicals on germinal mutations of unstable gene *mt-3a* (*Drosophila virilis*)[1] was investigated. Altogether 79,011 flies were examined and 3,617 mutants found.

Flies raised on food containing 0·1 per cent copper sulphate or on food made alkaline (*p*H 9–14) by means of sodium hydroxide, or flies from eggs and larvæ treated with sodium hydroxide or ammonium hydroxide, show a highly significant *decrease* of mutability; this was found both in mass and in individual cultures; the effect applies also to genes the mutability of which is influenced by other genes.

The chemicals themselves probably could not penetrate[2] into the nuclei of the germ cells, and therefore the decrease of mutability must have been the general effect of *disturbances* in the organism. A similar decrease of mutability in unstable genes, as a result of temperature disturbances, has been also reported[3,4].

Since in 'stable' genes similar chemical treatments result in an opposite effect (increase)[5], I reach the following conclusion: when a given physical or chemical disturbance is able to change the mutability, the *change* will be an *increase* in 'stable' (wild) genes where the natural selection favours the lowest feasible mutability-rate[6] (close to optimum stability); whereas, it will be a *decrease* in 'unstable' genes the mutability of which is close to the highest feasible (optimum unstability).

I wish to express my thanks to Dr. M. Demerec, Carnegie Institution, Cold Spring Harbor, for his valuable suggestions in the course of this work.

Physico-Chemical Nature of Bacteriolysis

WITHIN recent years, much attention has been paid to the antibacterial action of naturally occurring and synthetic products. The principal problem to be solved is that of the nature of the primary effect on the bacterial cell of the bacteriolytic or bacteriostatic agent. By such studies the intimate nature of the bacterial cytolysis may be illuminated and a practical means of early diagnosis of the lytic process may be forthcoming.

Hewitt[1] claims that visible lysis induced by the action of lysozyme is preceded by an activation of the bacterial dehydrases, this being shown by the fall in the aerobic redox potential of bacterial suspensions shortly after the addition of lysozyme. In support of this, Dr. Subkova in this Institute has shown that the oxygen uptake of bacteria (*M. lysodeikticus*) rises prior to the onset of lysis induced by lysozyme. No drift in redox potential occurs, however, when bacteriophage is added to bacterial suspensions.

Theoretical considerations led me to the opinion that the effects observed by Hewitt might be explained on the basis of the changes in *p*H occurring when lysozyme preparations (*p*H 7·2) are added to bacterial suspensions (*p*H 6·3–6·4). It can actually be shown that mere alkalinization of a bacterial suspension produces a negative potential drift, while acidification produces an opposite effect. By combining both kinds of procedure one may repeatedly

reproduce the course of the potential curve as pictured by Hewitt. Moreover, lysozyme inactivated by boiling causes the same change in redox potential as active lysozyme although no lysis occurs, and if the *p*H of the lysozyme is adjusted before addition to that of the bacterial suspension, no drift in redox potential occurs on mixing, though lysis takes place.

Since many of the most important properties of bacteria such as virulence, antigenic capacity, etc., reside in the surface layer, it was considered desirable to study the electrokinetic potential in relation to lysis. The experiments were made in collaboration with Dr. E. A. Moldavskaya, a Northrop microelectrophoretic chamber as modified by Abramson being utilized.

Preliminary experiments show that as soon as the lytic agent is added to a bacterial suspension, there is a sudden rise in the negative potential which persists for 5–10 minutes, after which the potential tends to return to the initial level. This phenomenon has been observed with lysozyme and in mixtures of *B. coli* and staphylococci with their respective phages. With *B. subtilis* the potential changes are in the opposite direction. The inactivated lytic agent does not produce any such effect, neither does the active agent affect the potential of quartz particles suspended in a similar medium. For bacteriophages the effect is specific.

The time relations of the potential changes are the same for lysozyme and bacteriophage. Since with lysozyme many of the cells are lysed instantly but with phage no detectable lysis occurs during the period occupied by the measurements, the possibility that the potential changes are produced by the adsorption of lytic products on to the surface of intact cells is eliminated. It may be concluded that the change in the potential of the bacterial surface accompanies lysis and is not due to an effect of contaminating impurities added with the lytic agent or to substances derived from lysed cells.

The study is being pursued in relation to bacteriostatic agents such as gramicidin and penicillin.

Antibiotics and Competition

IN the attention rightly directed towards the very great practical potentialities of the bacteriostatics, which the researches of Prof. H. W. Florey and his collaborators have done so much to develop, the scientific interest of these as part of the mechanism of competition is in danger of being ignored.

It may well be that water-soluble antibiotics are of widespread occurrence as one of the factors concerned in the competition of both lower and higher organisms occupying the same substratum.

In an address to the British Ecological Society in 1929, I directed attention to the very marked check to the growth of the root systems of higher plants which could result from the presence of other species. Afterwards the Canadian botanist Pavlychenko, employing a team of workers, was able to obtain quantitative expression for this phenomenon, and showed that in cereals the effect of competition on root growth might bring about a reduction to less than 1 per cent of that when competition was absent.

S. C. Varma, working in my laboratory, produced evidence that the depression of root-growth in competition was due to soluble substances and that the effects of these varied with the species concerned[1]. The same investigator employing various species of Hypericum obtained striking evidence not only of the individuality of the relation between species but also of the modifying influence of soil reaction upon the effect of competition on root development[2].

The evidence that Prof. Florey has obtained respecting the sensitiveness of penicillin to acidity or alkalinity may perhaps indicate one way in which reaction of the substrate may exercise its profound effects, not only on bacteria but also on higher plants. There is the possibility that the soluble antibiotics from the root systems of higher plants may have their practical applications; but the object of this letter is primarily to direct attention to the importance which these studies on antibiotics may have in elucidating the more fundamental aspects of the competition problem, a realization of which might well result in the accretion of valuable data.

Penicillin Dressings

Robinson and Wallace[1] have recently described a method of treating surface wounds with dressings of absorbent gauze inoculated with *Penicillium notatum*, the organism producing penicillin.

We have carried out preliminary experiments with a modification of this method, and the results (some two dozen cases have so far been treated) have been so astonishingly good that we feel wider tests are highly desirable. Large burnt areas covered with pus have cleared up in two or three days, and subsequent healing has been rapid.

Although the technique devised at the outset has given uniformly excellent results, further experiments are in hand to determine the optimum methods of production and application of the dressings.

We attach great importance to testing the bacteriostatic activity of each batch made, and to careful microbiological and clinical control throughout. With this proviso, the application of these dressings to superficial wounds appears to us to be free from risks; whether the method is suitable for deeper wounds is a matter for further research, and may present complications.

Dressings of the above type can quickly be prepared in large quantities, and at negligible cost.

Since one cannot predict how long will elapse before the industrial production of cheap, abundant and reliable penicillin, it appears to us that a fuller investigation of the 'live dressing' technique is a matter of the greatest urgency.

GESTURE ORIGIN OF INDO-EUROPEAN LANGUAGES

By Prof. ALEXANDER JÓHANNESSON
University of Iceland

AMONG the many theories which in course of time have been propounded on the origin of language, that put forward by Sir Richard Paget in his work "Human Speech" (1930) is one which is most probable, and likely, to revolutionize philology. In this work he asserts that the speaking organs imitated the bodily gestures, especially those of the hands, with which *Homo sapiens* some 30,000 years ago tried to make himself comprehensible and to understand his neighbours. This theory was put forward first in a treatise on the Polynesian language by Dr. J. Rae in 1862 (reprinted in "Human Speech"). Sir Richard Paget emphasizes that the natural sign-language of those born deaf, and that of the Red Indians, may give useful information as to the stages by which the human language was developed. It is evident that if the gesture theory is right, a valuable aid may be rendered by the study of sign-language all over the world.

I have for many years been occupied with a study on the same problem, and the University of Reykjavik has just published my work on the subject: "Um frumtungu Indogermana og frumheimkynni: On the primitive speech of the Indo-European people and their first home". I had nearly completed my work when I read Sir Richard Paget's book, and had not seen his other book on the same subject: "This English" (1935). As my researches had led me in a surprising manner along the same paths as Sir Richard had trod, I feel impelled to record the main results of my own investigations. Of the 2,200 Indo-European roots constructed by philologists, the most important class can be explained as an imitation by the speech organs of the movements of the hands, as the first man began to speak; another class consists of roots imitating the sounds in Nature, the crying of animals, the whistling of the wind, the roaring of the sea, etc.; a third part, which is insignificant, is due to the spontaneous utterances of emotions, such as laughing, weeping, coughing, sneezing, etc.

On the basis of these fundamental conclusions, I have built up a system which embodies the labials, the dentals, the liquids and the gutturals. If the theory is correct, words beginning with labials ought to signify to babble, to keep, to retain and to destroy, if the lips are closed (for example, English flap, babble, blather; fat, fadge (= bundle); Lat. paciscor; O.E. beadu, "battle"; Lat. findo; English boat, bang, barrow). If the lips are open, the labials mean to emanate, to respire with noise (Greek πιμπρημι, πνεω; O.E. fnæsettan), and if the cheeks at the same time are puffed out, to inflate, to distend (Lat. pollex; English pat, bole, pit, bud, bold, etc.).

The roots beginning with dentals have a similar meaning, as the first man either pressed his teeth together, or let the tip of the tongue rest against them: to touch or retain (Lat. tango; English thrive, take), to destroy (English thwite (=cut chips), thong, tough, dingle, dangle), to extend and to draw (in this case the tongue has been drawn back from the teeth to the palate: Lat. tenere, ducere; English thin, tight, teem), and finally to shudder (if combined with *r*, which was originally cacuminal, hard and vibrating); English thread, thrave (=herd); Greek ἴρεω; Russian drožu, "shudder". In considering the consonants and the vowels combined, I have given a new explanation of the so-called "ablaut": the vowel *e* indicates originally an imitation of pointing at oneself (as *e* in Lat ego "I"), whereas *u* is the imitation of stretching out the hand to point at the other person (as *u* in Lat. tu, "thou"). The vowels *u* and *o* are similar and the variation of *e* and *o* (as seen especially in Greek) is to express what is present and absent in time and space. For that reason *e* is predominant in the present tense and *o* in the past. The vowel *i* means something little, as has already been shown by many philologists (Otto Jespersen and others). If *e* is combined with an *i*, the ablaut *ei* (comp. Greek ει) means something emanating from *e* (myself), which is significant for the first class of the strong verbs. A very great proportion of all strong verbs of the first class mean to remove from some one: Greek κιω; Lat. eo, ivi "to go"; English write, glide, etc. The "ablaut" $e + u$ is an oral imitation of a circulating movement, and therefore a great many of the second class of strong verbs signify something round, as Greek κῦμα, "sea"; English cudgel (from kuggila-), cog, kite (from kyte, "a round stomach"), cob, hoop, etc.

The consonant *s* is an imitation of sounds in Nature, such as the running of water, the howling of the sea, the whistling of the wind. Of 330 Indo-European roots beginning with *s*, 93 show the meaning: (1) to flow (of water) as sea, cinders, (O.E. sinder), stale, snite (= blow the nose), stream; Greek αἷμα (from saima, "blood"; Lat. serum; Serbian sipiti, "flows out"; Celtic sruaim, "stream", etc.; (2) to put in motion (of water or fluids) as Lat. salum "swelling sea"; O.E. séoðan (German sieden), Greek ῥόδος (from σρόδος) "waving sea", etc.; (3) to fetch up or drink: swell (German schlucken); (4) every sort of movement: to creep, glide, curve, turn, throw, shake, pull, contract, dangle, let fall: seal (German Seehund), snake, slide, sledge, slough, swipe, swim, shoot, scrag, shrimp, sparkle (O.E. spurnan, sow), sag, etc. The roots beginning with a guttural signify "to gape" (in the beginning "to open the mouth", to receive food) as chew, gag, Lat. hio, gustus, etc. The roots beginning with liquids (*r* or *l*) have varying meanings. The *r* roots especially signify to make noise (roar; Sanskrit rásati, "cries"; Greek ῥῆμα, "speech, word"), to put in movement (Lat. rabies, rota; English run, rise), to tear (English rot; O.E. rift; Lat. rima, rumpo), to stretch, to erect (reach, right, rank; Lat. rex, rogus). The imitation of the gestures of the hand is evident in the roots with *r*, which signify to erect: in those roots formed with $r +$ vowel (*e* or *i*, as *i* is a high vowel) + guttural the tongue is moved upwards to the palate. The roots beginning with *l* signify especially "to move, to withdraw" (lode, last; Lat. lira, comp. delīrus), to glide slowly (Lat. libo, liqueo; English liquid), to lie without movement (lie; Lat. lacus), to lick (Lat. labium; German lecken; O.E. liccian) and to play (little, lungs, light; Lat. lacertus, "arm"—the tongue plays against the palate).

After having examined the onomatopoetica (imitations of different cries of animals as birds, dogs, wolves, frogs, sheep, cats and pigs and those imitating every sort of noise), the total number of roots thus explained comes up to 500, or nearly a quarter of the whole material. Those 500 roots are the first basis of the Indo-European languages. They all have a concrete meaning, whereas most of the others are abstract. It is the object of further investigations

to show how the roots with concrete meaning have developed an abstract meaning. The aim of philology in the last hundred years has been to investigate every language of the Indo-European family and, of course, many others in order to collect a great store of words and compare them for the purpose of reconstructing the Pregermanic language as well as the Indo-European, to find out the laws, which at all times cause the changes of forms, meanings, etc. Philologists have been satisfied with massing together an immense store of knowledge. Philology must become a scientific study in the sense of Darwin's theory, and every group of languages in the world must be investigated on the same principles of evolution. I am convinced, having worked in philology for more than thirty years, that no explanation of the origin of languages is acceptable except the gesture theory, an imitation of the gestures of *Homo sapiens*, before he learned to employ his speech organs. The difficulties which arise in investigating languages such as Chinese, Japanese, etc., on these principles of imitations, are due to the fact that the change of form of a gestural word is usually the result of making the original gesture in a different manner. A long time must elapse before philology is led into these new paths. Philologists, like many others, have a fear of being thought unorthodox and prefer to walk on well-beaten paths.

BRITISH SOCIETY OF ANIMAL PRODUCTION

FOR many years there has flourished in the United States a Society of Animal Production, which has recently started to publish a full journal, the *Journal of Animal Science*. Similar societies have been formed in other countries, and on January 6, a corresponding British organization came into being. Much of the future organization of the Society was left to a provisional committee comprising Dr. John Hammond—who took the chair at the opening meeting—Prof. Wm. C. Miller, Prof. R. G. White, Dr. A. B. Fowler and Messrs. Alec Hobson, James Mackintosh and W. A. Stewart. Dr. J. E. Nichols, who had been responsible for most of the preliminary arrangements, was elected secretary-treasurer.

The opening meeting, held at the London School of Hygiene and Tropical Medicine, took the form of an all-day discussion on cattle-breeding policies, and the subject-matter was appropriately divided up into dairy cattle, dual-purpose cattle and beef cattle. In each section there was an opening paper, followed by a discussion.

Reading the paper on dairy cattle, Dr. Joseph Edwards compared present-day policies in Great Britain with the much more enterprising schemes in the United States. Artificial insemination is providing a real contribution to mass improvement schemes in the United States and, during 1943, the Artificial Insemination Society had arranged the servicing of 182,524 cows by 574 bulls. This is to be compared with the total of only 41,500 cows serviced by no fewer than 1,230 bulls in the co-operative Dairy Bull Associations. Dr. Edwards recently accompanied Mr. J. N. Ritchie, of the Ministry of Agriculture's veterinary service, on a survey of artificial insemination practices in the United States and would shortly submit with him a comprehensive report on the subject.

By whatever means the dairy farmer obtains improved stock, one point is fundamental, namely, that better breeding calls for better environment, if the improved genetic potentialities are to be exploited. It is noteworthy that most members of the American artificial insemination societies now feel that they have dairy cattle worthy of attention, and are demanding information on all up-to-date husbandry methods. It is desirable that the breed societies in Great Britain should play a much more important part in pedigree breeding than they are doing at present. In the United States, agreement between the dairy cattle breed societies has been attained on such matters as uniform rules for registration of cattle bred by artificial insemination and type-judging for all breeds. They also support research work destined to help them, for example, on the blood-typing parentage test, and they keep the bulk of pedigree records. In Great Britain, the élite dairy herds are a heritage and should be carefully protected against dispersal, besides being utilized for statistical research.

The paper on dual-purpose cattle was read by Mr. W. S. Mansfield, who stressed how animals of this type fit into mixed farming such as that practised by himself at the University Farm, Cambridge. In his own case, milk sales form the second largest item and yet are responsible for only one seventh of the total net sales, which are otherwise composed of returns from corn, potatoes, sugar beet, seed, mutton, pork, beef, horses and poultry. Cows on such a farm must be capable of (1) converting bulky by-products into milk; (2) making manure for the arable land; and (3) breeding heifer-calves worth rearing for the dairy and bull-calves worth rearing for beef. Such functions can be performed satisfactorily only by dual-purpose cattle.

Unfortunately, there is a dearth of dual-purpose cattle, and methods now adopted do not permit of breeding true. The only real solution is to practise inbreeding or long-continued line-breeding. Careful management of dual-purpose heifers is most important: it is almost impossible to do the heifer calves too well for the first six months of life, because, if they are then transferred to a much lower plane of nutrition, they will continue to grow well for another eighteen months, will be ready to mate at twenty months, and at calving will be as large as heifers six to nine months older that have been fed inadequately as calves.

Mr. W. A. Stewart, reading the paper on beef cattle, dealt first with sources of supply, and stressed that, on lowland farms, it is most uneconomical to rear only one calf per cow. Among methods of multiple rearing, there is that practised during the first half of the nineteenth century by Hugh Watson, of Aberdeen Angus fame; but there is also Mr. H. R. Overman's system, namely, bulling a certain number of heifers, selling the greater number when freshly calved, and rearing all the calves on those remaining.

Ley farming is likely to have beneficial effects upon the numbers and quality of beef cattle that could be fattened in certain areas, for example, the Welland Valley, where formerly graziers required old bullocks for the pastures but in future would be able to fatten younger cattle.

It is essential that the milk-producing qualities of British beef-breed cows should be increased. This can best be done by making full use of bulls that are proved 'getters', not only of offspring of a high standard of beef conformation and maturity, but also

of daughters that are good milkers. It is not impossible to aim at 300–400-gallon lactations even among cows of high-class beef type.

The Argentine markets have been responsible for the appearance in sale- and show-rings of a small, thick, fine-quality, fine-boned, short-legged type of animal. This is not necessarily the type desired by the average British farmer, and it is likely that a middle course will be adopted, and that animals will be produced which give reasonable weight for age but are early maturing. ALASTAIR N. WORDEN.

PLYWOOD ADHESIVES AND LININGS

ATTENTION has already been directed in NATURE to the important research work carried out in the Forest Research Institute, Dehra Dun, India, in connexion with the construction of plywood containers to replace metal drums and other containers imported in large quantities before the War, the incidence of the latter bringing this source of supply to an end. In connexion with this research, investigations had to be instituted into possible new adhesives. The Wood Preservation Section of the Institute has done important work on the development of maize and ground-nut proteins as adhesives, and on various lining compounds for proofing plywood containers and drums. The plywood and other industries have been affected by the shortage and high prices of casein, and this work on the protein of maize, which is a waste product of starch manufacture, will not only enable this waste product to be used but also will give an adhesive at a competitive price.

Two Indian Forest Leaflets (Utilization), Nos. 40 and 52 (For. Res. Inst., Dehra Dun, 1943), deal with plywood adhesives. In Leaflet No. 40 (Pp. ii+14. 9*d.*) the result of research has shown that prolamins, isolated from Indian cereals, are equally suitable for the preparation of water-resistant plywood adhesives. This type of adhesive can be prepared by adding to a 20 per cent suspension of prolamin in 80 per cent alcohol, 5 per cent of formaldehyde (40 per cent formalin). One per cent of ammonia or an organic acid such as acetic, tannic, etc., may be added as a catalyst. The adhesive suspension so prepared should be applied within twenty-four hours of its preparation. Veneers coated with these adhesives, after drying at room temperature, should be pressed together at a temperature of 250–300° F. for a suitable period (10 minutes for 3/16 in. plywood) at a pressure of 200 lb. per sq. in.

Leaflet No. 52 (Pp. ii+6. 5*d.*) deals with researches with the object of utilizing the wholemeal and proteins of sunn-hemp seed (*Crotolaria juncia*) for plywood adhesives. For commercial plywood (not requiring a high degree of water resistance) a wholemeal lime silicate formula with rosin, copper sulphate and tannic acid has been found suitable. With the protein, lime silicate and borax-formaldehyde formulæ have been found suitable for the preparation of water-resistant plywood.

Leaflet No. 49 (Pp. ii+10. 5*d.*) discusses the results of experiments on various types of inner linings suitable for plywood containers for storage of various commodities such as greases, liquids and so forth. A variety of inner coatings have been tried and tested; some were found good for certain materials, others for other contents, but a universal leak-proof coating has not yet proved attainable. The requirements demanded by such a lining are nearly as variable as the nature of the commodities themselves. The linings so far tried, nine in number, are: animal glue-treacle composition, prolamin formaldehyde glue, casein or vegetable protein-formaldehyde glue, paraffin wax, bituminous paint, shellac varnish, shellac-melamine composition, phenol-formaldehyde resin and cashew shell oil varnish. The methods of preparation and application of these linings are described in the leaflet.

LOCATING BURIED CABLES ELECTRICALLY

FOR the protection of buried inter-city cables against damage by lightning, it is sometimes necessary to install copper shield wires above a cable already in the ground, and the precise route of the cable must be determined so that the shield wires can be correctly placed. It is also important to know the depth of the cable, so that damage to it may be avoided while installing the shield wires. This can now be done electrically with a simple device which consists of coils that pick up a tone which has been applied to the cable sheath. The device is described in an article by R. M. C. Greenidge (*Bell Lab. Rec.*, 22, No. 3; November 1943).

The device carries three coils, a fixed locating coil A, a fixed direction coil B and a pivoted depth coil C mounted on a crossbar attached to a vertical rod which supports a graduated quadrant scale S and has a spirit-level on its upper end. A handle is used to adjust the apparatus by forcing a spike into the ground. A selector switch connects any one of the three coils to an amplifier and detector circuit, which is multiple connected to the coil circuits. A pointer P indicates the setting of the depth coil C, and a shaft which slides vertically permits levelling the apparatus.

The test current is generated by the buzzer of a 20C. test set. One of its terminals is connected to the cable sheath at a pressure-testing valve and the other to an earth rod located 50–100 ft. from the cable. Current flows along the sheath in both directions, and through earth to the earth rod. With the amplifier in operation and earphones used as detector, the selector switch is set to close the locating coil circuit and the apparatus is carried across the path of the cable. When coil A comes directly over the cable, a null position is reached, and at this point the spike is pushed into the ground. By setting the selector switch to close coil B circuit and rotating the apparatus round the spike, the null point of coil B is found. In this position the horizontal bar on which coil C is located is at right angles to the path of the cable. Adjusting the sliding shaft then levels the device, after which the selector switch is set to close coil C circuit and the depth coil rotated on its pivot for the null point. The reading on the scale, as indicated by the pointer, is the distance of the centre of the cable below the surface. If r is the radius of the cable, h the height of the coils above the ground, l the distance between the coils A and C, and d the depth of the cable, $d = l \cot \theta - k$, where $k = r + h$ and θ is the angle which the pointer P makes with the horizontal when coil C is in its null position. By this formula the quadrant scale S can be calibrated for depth.

The depth indicator is usually handled by a team

of three men. Where the cable is buried to a depth of 25 in. or more, measurements are taken every 50 ft. and flags are placed to mark the path of the cable. As a check on the accuracy of the survey and also of the guiding of the tractor and plough used for laying the shield wires, test holes are dug at intervals to expose the wires and cable after the plough has passed. In most cases the two wires are found to straddle the cable almost exactly and are about 4 in. distant on each side, but in some instances they are off centre by 2–3 in. As a result of the depth survey and the precautions during the ploughing, damage to the cable is completely avoided.

FORTHCOMING EVENTS

(*Meetings marked with an asterisk * are open to the public*)

Saturday, February 5

NUTRITION SOCIETY (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 10.30 a.m.—Conference on "Budgetary and Dietary Surveys of Families and Individuals", Part 1.

GEOLOGISTS' ASSOCIATION (at the Geological Society of London, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Sir Edmund O. Teale: "The Geology and Scenery of Tanganyika Territory, East Africa".

INSTITUTE of PHYSICS (MANCHESTER AND DISTRICT BRANCH) (at the Christie Hospital and Holt Radium Institute, Wilmslow Road, Withington, Manchester), at 2.30 p.m.—Prof. W. V. Mayneord: "Physical Principles of X-Ray Therapy".

Monday, February 7

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 8 p.m.—Sir Robert Reid: "The Excluded Areas of Assam".

Tuesday, February 8

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 1.30 p.m.—Dr. Werner Kissling: "Eriskay" (Sound Film).

INSTITUTION OF CHEMICAL ENGINEERS (joint meeting with the CHEMICAL ENGINEERING GROUP) (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Mr. J. Arthur Reavell: "Infra-Red Radiation and its relation to Distillation and Evaporation Problems".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Prof. H. D. Kay: "Modern Developments in Dairy Science", iii. "Problems of Milk Distribution and Manufacture".*

INSTITUTION OF CIVIL ENGINEERS (STRUCTURAL AND BUILDING ENGINEERING DIVISION) (at Great George Street, Westminster, London, S.W.1), at 5.30 p.m.—Mr. W. E. J. Budgen: "Modern Computation Methods and Office Practice in the Design of Statically Indeterminate Structures".

ROYAL PHOTOGRAPHIC SOCIETY (SCIENTIFIC AND TECHNICAL GROUP) (at 16 Princes Gate, South Kensington, London, S.W.7), at 6 p.m.—Mr. H. W. Lee and Miss E. A. Neumann: "Surface Treatment of Lenses".

INSTITUTION OF ELECTRICAL ENGINEERS (LONDON STUDENTS' SECTION) at Savoy Place, Victoria Embankment, London, W.C.2), at 7 p.m.—Sir A. Stanley Angwin: "Recent Progress in Telecommunications due to the use of New Materials".

Wednesday, February 9

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Miss E. Strudwick: "Education To-day and To-morrow", 4: "Secondary Schools for Girls".

ROYAL SANITARY INSTITUTE (at 90 Buckingham Palace Road, London, S.W.1), at 2.30 p.m.—Discussion on "Rodent Infestation" (to be opened by Mr. W. McCauley Gracie).

SOCIETY OF CHEMICAL INDUSTRY (NUTRITION PANEL OF THE FOOD GROUP) (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Mr. F. A. Robinson: "The Vitamin B_2 Complex—Some Recently Characterised Components".

INSTITUTION OF ELECTRICAL ENGINEERS (TRANSMISSION SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5 30 p.m.—Mr. B. L. Metcalf: "Transmission and Distribution of Electricity to Mines".

Thursday, February 10

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Sir Lawrence Bragg, F.R.S.: "The Strategy and Tactics of Crystal Structure Analysis by X-Rays".*

KING'S COLLEGE (in the Department of Electrical Engineering, Strand, London, W.C.2), at 3 p.m.—Mr. W. D. Horsley: "Turbo Generator Practice".*

INSTITUTE OF PHYSICS (ELECTRONICS GROUP) (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Prof. J. D. Cockcroft, F.R.S.: "Cyclotron and Betatron".

INSTITUTION OF ELECTRICAL ENGINEERS (INSTALLATIONS SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Dr. H. Barron, Mr. J. N. Dean and Mr. T. R. Scott: "Thermoplastic Cables".

ROYAL AERONAUTICAL SOCIETY (at the Institution of Mechanical Engineers, Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Mr. E. T. Jones: "Flight Testing Methods".

PHARMACEUTICAL SOCIETY (at 17 Bloomsbury Square, London, W.C.1), at 7 p.m.—Dr. A. J. Ewins, F.R.S.: "Progress and Problems of Chemotherapy" (Harrison Memorial Lecture).

Friday, February 11

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5 p.m.—Prof. G. Ingle Finch, F.R.S.: "Wear of Surfaces and Lubrication".*

INSTITUTE OF PHYSICS (LONDON AND HOME COUNTIES' BRANCH) (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 6 p.m.—Annual General Meeting. Discussion on "The Mathematical Needs of the Physicist" (to be opened by Prof H. Levy).

Saturday, February 12

SHEFFIELD METALLURGICAL ASSOCIATION (at 198 West Street, Sheffield), at 2.30 p.m.—Dr. G Jessop: "Some Electro-chemical Methods of Analysis".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

AGRICULTURAL ASSISTANT to the Agricultural and Horticultural Organizer—The Clerk to the County Council, Shire Hall, Bedford (February 11).

MASTER to teach mainly MECHANICS in the Junior Technical School of Coventry Technical College—The Director of Education, Education Offices, Coventry (February 11).

GRADUATE TEACHER (full-time, temporary) OF ENGINEERING SUBJECTS—The Principal, Twickenham Technical College, Egerton Road, Twickenham, Middlesex (February 12).

ASSISTANT MASTER (full-time, graduate) qualified to take GENERAL ENGINEERING SUBJECTS in the Junior Technical School and MECHANICAL ENGINEERING SUBJECTS up to Ordinary and Higher National Certificate standard in the College senior part-time courses—The Principal, Southall Technical College, Beaconsfield Road, Southall, Middlesex (February 12).

ASSISTANT LECTURER IN PHYSICS—The Registrar, University College, Nottingham (February 12).

HEAD MASTER—The Clerk to the Governors, Sir Joseph Williamson's Mathematical School, 116 High Street, Rochester (February 12).

DEPUTY BOROUGH ENGINEER AND SURVEYOR—The Town Clerk, Town Hall, Ilford (endorsed 'Deputy Borough Engineer') (February 15).

SPEECH THERAPIST—The Chief Education Officer, County Offices, Chelmsford, Essex (February 15).

GRADUATE TEACHER (temporary) OF SCIENCE OR MATHEMATICS, and a TEACHER (temporary) OF ENGINEERING SUBJECTS—The Principal, Luton Technical College, Park Square, Luton, Beds. (February 15).

BIO-CHEMIST—The Medical Officer of Health, 68 St. Giles' Street, Norwich (February 16).

ASSISTANT LECTURER AND DEMONSTRATOR IN CHEMISTRY—The Registrar, University College, Leicester (February 21).

PRINCIPAL of the Brighton Technical College—The Education Officer, 54 Old Steine, Brighton 1 (February 21).

LABORATORY ASSISTANT IN THE DEPARTMENT OF BOTANY—The Secretary, Bedford College for Women, Springfield, Sidgwick Avenue, Cambridge (February 26).

LECTURER (man or woman) in the DEPARTMENT OF GEOGRAPHY—The Secretary, Bedford College for Women, Regent's Park, London, N.W.1 (March 1).

UNIVERSITY LECTURER IN ANTHROPOLOGY—The Secretary of the Appointments Committee, Faculty of Archæology and Anthropology, Museum of Archæology and of Ethnology, Cambridge (April 15).

COLLIERY SURVEYOR for the Nigerian Government Collieries—The Ministry of Labour and National Service, Appointments Department, Sardinia Street, Kingsway, London, W C.2 (quoting Order No. O.S.20).

MINE MANAGER and ASSISTANT MANAGER for an underground Chrome Mine in New Caledonia (South Pacific)—The Ministry of Labour and National Service, Appointments Department, Sardinia Street, Kingsway, London, W.C.2 (quoting Order No. O.S.17).

LECTURER IN THE DEPARTMENT OF OCEANOGRAPHY—The Registrar, The University, Liverpool 3.

LECTURER (full-time) OF MATHEMATICS AND SCIENCE at three Boys' Junior Technical Schools—The Director of Education, Education Offices, 14 Sir Thomas Street, Liverpool 1.

LECTURER (full-time) IN MECHANICAL ENGINEERING to teach to Higher National Certificate standard—The Principal, Wimbledon Technical College, Gladstone Road, London, S.W.19.

MASTER FOR ENGINEERING WORKSHOP PROCESSES AND PRACTICE—The Principal, County Secondary School and Cumberland Technical College, Workington.

GRADUATE ASSISTANT to teach MATHEMATICS AND SCIENCE, a GRADUATE ASSISTANT FOR JUNIOR ENGINEERING SUBJECTS in Technical Day School and ordinary National Certificate Subjects in MECHANICAL ENGINEERING in Technical College, and a GRADUATE ASSISTANT for Subjects up to Higher National Certificate standard in MECHANICAL ENGINEERING and be able to teach ELECTRICAL ENGINEERING up to ordinary National Certificate standard—The Chief Education Officer, Education Offices, West Hartlepool.

PHARMACIST FOR THE GOVERNMENT OF NORTHERN RHODESIA HEALTH DEPARTMENT—The Secretary, Overseas Manpower Committee, Ministry of Labour and National Service, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. 1252).

THE ROYAL OBSERVATORY

THE announcement in the daily Press that the Admiralty has decided, in principle, that the Royal Observatory shall be moved from Greenwich to a new site, where conditions are more favourable for astronomical observations, will not have come as a surprise to those who have watched the trend of events in recent years. Rather is it a matter for surprise that the Observatory has been able to carry on for so long, under conditions of increasing difficulty, on its original site. Many observatories elsewhere have been compelled by similar circumstances to move. In the case of the Royal Observatory, the long associations with Greenwich, the advantages in fundamental astronomy of continuity of observation on the same site and with the same instruments, and its position on the prime meridian, have no doubt all played a part in postponing a decision the ultimate inevitability of which must long have been apparent.

The Royal Observatory was founded in 1675 by Charles II, to meet the needs of navigation. The problem of finding longitude at sea had then become urgent. The positions of the moon and stars were not known with sufficient accuracy to enable the method of lunar distances to be used. The Royal Warrant for the building of the Observatory states that "in order to the finding out of the longitude of places for perfecting navigation and astronomy, we have resolved to build a small Observatory within our park at Greenwich, upon the highest ground, at or near the place where the Castle stood". Sir Christopher Wren was appointed as architect and the Rev. John Flamsteed was appointed "our astronomical observator" and directed "to apply himself with the most exact care and diligence to the rectifying the tables of the motions of the heavens, and the places of the fixed stars, so as to find out the so-much-desired longitudes of places for the perfecting the art of navigation".

This branch of astronomy has continued to be the fundamental work of the Observatory throughout its long history. It provides the foundations upon which so much astronomy is built. The importance of the contribution made by Greenwich was stressed by the eminent American astronomer, Simon Newcomb :

"The most useful branch of astronomy has hitherto been that which, treating of the positions and motions of the heavenly bodies, is practically applied to the geographical positions on land and at sea. The Greenwich Observatory has . . . been so far the largest contributor in this direction as to give rise to the remark that, if this branch of astronomy were entirely lost, it could be reconstructed from the Greenwich observations alone."

When the need had arisen for general agreement about the choice of a zero or prime meridian from which longitudes should be measured, and a conference was called in Washington in 1883 by the State Department of the United States to consider the question, no alternative to the meridian through Greenwich was seriously considered. By an almost unanimous vote, the meridian through the centre of

the transit instrument of the Greenwich Observatory was adopted as the prime meridian and as the basis for a zone time system. The choice of Greenwich was due to the close concern of the Observatory for more than two centuries with the practical needs of navigation.

The work of the Royal Observatory has not, however, been restricted to fundamental astronomy. In Airy's time meteorological, magnetic, solar and spectroscopic observations were added. Meteorological and magnetic observations were commenced in 1840. The Royal Observatory has the longest continuous series of magnetic observations and was the first observatory to employ photography, in order to obtain continuous records of the variations of the earth's magnetism. The magnetic observations were removed from Greenwich to Abinger, in Surrey, in 1923, consequent upon the electrification of the suburban system of the Southern Railway. The Solar Department, added in 1873, was a natural development arising out of the discovery that there were certain definite relationships between terrestrial magnetism and phenomena on the sun. In 1886, the 28-in. refractor was added to the Observatory's equipment, for visual spectroscopic observations and for double-star measurements. The application of photography to astronomy opened many new fields of work, and the Royal Observatory has taken a prominent part in the work of the Astrographic Catalogue, in the measurement of stellar parallaxes, in the determination of magnitudes and proper-motions of stars, in the measurement of colour temperatures and in other important investigations. A 26-in. photographic refractor, a 30-in. reflector and a 36-in. reflector have been added to the equipment of the Observatory at various times.

When the Royal Observatory was built, Greenwich was a fashionable village in the country, several miles from London. It was many years before the outward growth of London, with its accompanying pall of smoke, began to be troublesome. In 1824 Pond, then Astronomer Royal, erected an azimuth mark at Chingford for the new Troughton transit instrument. It must have been possible at that time to observe this mark with fair regularity; but it is many years since it has been visible from Greenwich even under the best conditions. The first note of concern about the future appears in the report of the Astronomer Royal (Sir William Christie) to the Board of Visitors of the Royal Observatory in 1906: "The continued efficiency of the Observatory is seriously threatened by the schemes for generating stations planted, or to be planted, in the immediate neighbourhood of the Observatory." The London County Council was then building a generating station exactly on the Greenwich meridian, half a mile from the Observatory and overshadowing the noble buildings of the Royal Naval College. That a public authority should have been allowed to commit such an act of vandalism is a reproach to the nation. The two chimneys, which stride the meridian, were indeed truncated to reduce the interference from smoke and heated gases with observations of circumpolar stars below the pole. Nevertheless, this generating station has been a source of continual trouble, discharging smoke and fumes and, with a northerly wind, showering grit over the Observatory, which has caused damage to pivots and other delicate parts of the instruments.

At the close of the War of 1914–18, there were still green fields and country lanes within an easy walk of Greenwich in the south-east direction. But since then London has stretched its tentacles well beyond Greenwich and, during the same period, there has been considerable industrial development in the vicinity of the River Thames. The deterioration of conditions for observation during the past twenty-five years has been marked and progressive, and has been referred to in the annual report of the Astronomer Royal on several occasions. The measurement with an Owens automatic filter of the pollution of the atmosphere by solid matter was commenced in 1934 and has shown that the pollution at Greenwich is not surpassed, on the average, at any reporting station in Great Britain. The difficulties were summarized in the Astronomer Royal's report for the year 1939.

The progressive decrease in the transparency of the atmosphere at Greenwich is shown by comparison between the Greenwich and Kew annual sunshine totals. From 1911 until 1920, Greenwich averaged sixty-four hours more sunshine than Kew; thereafter there was a rapid relative decrease in the Greenwich totals, so that during 1936–38 Kew averaged 159 hours more than Greenwich. This decrease in the amount of sunshine recorded at Greenwich in relation to the amount recorded at Kew is the result of loss of register at Greenwich when the sun is low, caused by atmospheric impurity.

A further trouble, first referred to in the report of the Astronomer Royal for 1937, was the brightness of the sky resulting from scattering of light from street lamps and illuminated advertisement signs; modern developments in street lighting, such as mercury vapour lamps and high-pressure gas, to meet insistent demands for better road illumination, have made the night sky at Greenwich (in peace-time) so bright that the Milky Way is never visible with the naked eye and long-exposure photography has become impossible. All types of observation, both visual and photographic, have been adversely affected; some, such as photometric observations, which require uniform transparency of the sky in different directions, can no longer be undertaken. New types of instrument, such as the Schmidt camera for the photography of faint stars, cannot be used at Greenwich because of the fogging of the plates.

It should not be necessary for a scientific establishment—even though it is the oldest in Great Britain—to stand out against public amenities. The astronomer requires a dark sky and a clean atmosphere; the public wants well-lit roads and puts up with a polluted atmosphere as the penalty of urbanization. The staff of the Royal Observatory has for many years been waging an unequal and losing struggle against progressively worsening conditions. It is not right that the reputation and prestige of the Royal Observatory should suffer by having to turn back

from the van of progress in astronomy. The contributions that the Observatory has made to astronomical and nautical science in its long history, and the prestige that it has brought to the British nation, give it a right to ask for a new and a worthy home, where it will be free from the troubles that have so sorely beset it and where it may enter upon a new era of service to the community and of scientific achievement.

The Paris Observatory, faced with somewhat similar problems in a much less acute form, set up its large telescopes at Meudon and established a high-altitude station at the Pic du Midi. The possibility of keeping the meridian work and the time service at Greenwich and moving the rest of the work has evidently been considered and rejected. The meridian observations are handicapped and their accuracy is impaired by the difficulty of observing low north stars. The long-range programmes of observation, which should be undertaken by a great national observatory, require every member of the staff to observe, usually with more than one instrument; division into two branches would entail a serious loss of flexibility. The Observatory need not necessarily be tied to the prime meridian, which has been fixed by international agreement and will remain. The War has already necessitated the removal of the time service from Greenwich, and Greenwich time is now being provided by two time stations, neither of which is on the Greenwich meridian.

It is to be hoped that the original building, which Wren said that he built "a little for pompe", and the old buildings clustered around it will remain and that the historic instruments—including Halley's, Bradley's and Pond's transits, Bradley's zenith sector, with which aberration and nutation were discovered, the old quadrants, and, most famous perhaps of them all, the Airy transit circle—will be suitably displayed in them. They will become an object of pilgrimage not merely to astronomers but also to many visitors to Great Britain from all parts of the world.

Much of the work of the Royal Observatory has had to be removed elsewhere during the War, either for reasons of security or because of enemy action. The continuity of many programmes of observation has been broken. It is to be hoped that a new home will be made available as soon as conditions permit, so that the various branches of the Observatory can be brought together again and normal work resumed under more favourable conditions. It is understood that Treasury sanction will be required; but surely in a case such as this, to obtain it will be little more than a formality. The new home should be one befitting the long history and great traditions of the Royal Observatory. What could be more appropriate than that one of our large historic country houses, mellowed with age and rich in associations with the past, should form the nucleus of the new Observatory, the various telescopes being erected in the surrounding grounds? A fundamental need is for a neighbourhood not likely to be affected by the spread of industry, and it should not be impossible to find such a site.

A TURNING POINT IN EDUCATION

Education in Transition

A Sociological Study of the Impact of War on English Education, 1939–1943. By H. C. Dent. (International Library of Sociology and Social Reconstruction.) Pp. xi+244. (London: Kegan Paul and Co., Ltd., 1944.) 12*s.* 6*d.* net.

THE Education Bill now before Parliament is remarkable in many ways. The complete break it effects with the traditions of a century is enough to justify a description of it as revolutionary. Yet support for it is well-nigh unanimous, and criticisms offered during the second reading debate were confined to relatively minor points.

What is most remarkable about all this is that it should have been possible to introduce such a Bill at all, let alone to do so amid such general approval. It would have been inconceivable even as recently as three years ago.

Evidently some profoundly important change of outlook has occurred in Great Britain within a very short time. The new sense of educational needs is obviously a result of this deeper and wider change. It might well have happened eventually without the shock of total war. But the shock has certainly accelerated it and given it both sharper definition and, for the time being at least, a powerful backing of national conviction.

Essentially the change is towards a new conception of national destiny both in internal life and in external relations and responsibilities. It is British society as a whole which now tends to think so differently of itself. That the changed outlook should find expression first and most prominently in a liberally inspired plan of educational reconstruction is both natural and significant. The quickened sense of destiny and new life comes to its logical focus there, and Mr. Dent is well justified in the suggestion he offers in the subtitle of his book.

What is needed then, at such a turning point, is a backward glance with a critical eye over the past four years to mark out the route we have travelled. Mr. Dent is very favourably placed and unusually well qualified to perform this service, and he has discharged it with grasp and understanding in a timely and competent book. Though he writes with both warmth and insight he shows no tendency to dramatize the story. Yet the material itself is so intensely dramatic, passing as it does from the nerveless and sluggish Britain of the last decade to the sinewy and expectant Britain of to-day, that, in effect, it dramatizes itself.

The author tells his story in four stages, beginning with the mass-evacuation of children upon the outbreak of war. These are: disintegration, recuperation, adaptation and ferment. How strongly this suggests a five-act play of which the final act is still to be played! One could wish that something of this sense of drama on the great national scale might be communicated to those numerous critics of the Education Bill who see in it not at all the earnest of a great awakening but merely a failure to give full effect to some petty or short-sighted interest of their own.

Disintegration is, of course, the story of the disastrous consequences of hasty and ill-planned evacuation, planned it would seem by those who had little or no concern for educational consequences but were only eager to get the children away from the danger-

areas. Yet this very bungling contributed in a most effective way to the awakening that was to take place. As Mr. Dent very truly observes: "It was a striking illustration of the sociological rule that the significance of an institution of society only becomes appreciated in a marginal situation".

The "it" here is the effect of evacuation in setting so many people thinking seriously about national education for the first time in their lives; the "marginal situation" is the shock of close contact between sections and classes of the population which had hitherto been almost totally ignorant of one another. Much was to happen as the result of this, the redeeming effect of what was otherwise so nearly disaster.

Recuperation followed through efforts from two main sources. One was the devoted work of an army of teachers and officials. To these Mr. Dent does ample justice. He does rather less than justice to the other, to the Board of Education itself. No doubt the Board, like so many other authorities, was lacking in grasp and foresight at the outset. But it had no free hand and was constantly being pushed aside or over-ruled. It is probably no accident that recuperation proceeded *pari passu* with recovery by the Board of its own proper controls and responsibilities.

Adaptation is a longer story. It became possible in the respite that was accorded us in 1941. The point that Mr. Dent makes with much force here amply justifies the title of the story. After mentioning the headings of the developments that occurred: war-time nurseries, school-meals, camp boarding schools, service of youth, pre-service training, youth registration, and several others, he comments: "Not a single one of these developments is wholly new. Powerful as has been the stimulus which total war has given to educational thought in this country, in the realm of educational practice it has as yet brought into being no absolutely new form or institution", though he believes that in the realm of theory we are now reaching new territory. The observation is just. What was working at this stage was the characteristic English 'hunch', inchoate thought revealing itself first in improvising action.

Then, very fruitfully, and again quite characteristically, follows the ferment, which has been going on so vigorously for the last year or two, expressing itself in a flood of books, pamphlets, brochures, articles and other forms of declaration. Mr. Dent gives an able analysis of this material, showing conclusively how the thinking, while almost invariably quite practical, was all the time deepening and widening and establishing ever firmer grasp.

So, in effect, the essential revolution had already taken place when the Board, seizing the happy moment, issued first its White Paper and then its draft Bill.

The full moral of the story has yet to be drawn. One important aspect of it is well stated by the Archbishop of Canterbury in a passage that Mr. Dent quotes: "The educational problem must never be separated from the social problem. It is all part of the great enterprise of civilization—the provision of a truly civilized society". But, as Mr. Dent so clearly sees, it is for the British people themselves to draw the full moral. The moment is big with fate. The Bill at its best, even when it has become an Act, offers no more than a great opportunity. We still have to learn new restraints and to subordinate the lesser to the larger interests if we are to make full and fruitful use of the instruments it places in our hands. FRED CLARKE.

SOCIAL PSYCHOLOGY IN A WAR FACTORY

War Factory

A Report by Mass Observation. Pp. 127. (London: Victor Gollancz, Ltd., 1943.) 4*s*. 6*d*. net.

WHAT'S in a name? More now than in Shakespeare's time. To attract notice, a label is necessary for any new movement, yet its later directions may be inaccurately described by the original title. It might shock some gentle English socialists to realize why there is a 'z' in Nazi, or organizers of O.C.T.U.s to discover an early meaning of 'cad'.

"War Factory" is "a Report by Mass Observation". Yet it is not by the masses, and Mr. J. B. Priestley would deny that it is of the masses. Perhaps because of this, it reads unusually well. Here is a workmanlike account of 'functional penetration' or 'participant observation'. This technique anticipated Mass Observation; a fact acknowledged with some back-hand swipes by Mr. Tom Harrisson in an interesting, splenetic preface. He shows gratifying signs of dropping a tiresome tendency to quote only work by the 'old firm'; yet it is still true that science, like a house, is built by superimposing stories, not by ballet-leaps deriving momentum from kicks at the work of predecessors. Mass Observation has still to work itself into the corpus of science. In this attempt, spinosity of style will accomplish merely punctate, superficial penetration.

"War Factory" is well written by a mother; a Cambridge graduate, less ambivalent towards social differences than many educated authors, with an ear almost untitillated by odd dialect and bad language. Any temptation to dazzle the B-class—as market-researchers put it—has been resisted.

The observations were made unobtrusively while the author worked in a small factory. Here only two managers knew that the workers (and themselves) were being studied. Part of the factory was an altered private house, situated neither in a large town nor in the north of England. It is hoped that the politically minded, on reading this, will not decide that the book can therefore be neglected; even these workers are God's creatures; and in the country, geographical and social differences significantly affect workers' attitudes.

Most of the employees described are young country girls with no industrial tradition, 'directed' to a new, chimneyless and socially 'rootless' factory. Character-sketches are given; they are salutary reading for machine-worshippers who ignore individual mental differences, though subject to the methodological criticism that such novelistic or journalistic efforts may cast as much psychological light upon the writer as upon the person described. Even in this little congeries—apparently it never grew into a community—there was marked social stratification. Girls in the machine and the assembly shops were regarded in very different lights. Nearly all, however, spoke of those who gave orders and did domestic work as 'they': and those who obeyed and were cared for solicitously as 'we'; a sobering thought for democrats.

The investigation was paid for by the firm observed; unlike the studies reported in "The Pub and the Public". This fact must be taken into account in appraising the result. The observer's criticism, however, was accepted sportingly and broadmindedly,

in a constructive spirit. Indeed, the footnotes, by the works and labour managers, sometimes re-interpreting the writer's findings, but usually agreeing with them and accepting their practical implications, are some of the most encouraging parts of this book. Has the admirable "Western Electric attitude", which regards differences between the personality and temperament of workers, even in engineering shops, as suggesting scientific problems, spread at last from the United States to England ? North of the Trent we await the dawn.

In this book there are no Zolaesque revelations, no 'front-page' stuff. Some newspaper men will be disappointed in this factory, for no men bite dogs. It offers no foundation for a glossy propaganda film or husky radio-postscript. We find just a detailed account of how a bunch of country girls worked, or didn't, in this comfortable, rather pleasant war-factory; how they adapted themselves, or didn't, to the bench and the hostel; how they solved the 'academic' problem of rest-pauses by just taking them when 'so disposed'; how they displayed almost no interest in the War, except to speculate what they would do when it was over, thus puzzling tidy-minded 'scientific' thinkers, who regard the War as 'a stimulus', like a spur or a tot of rum. Now, this attitude will annoy people who, having delighted to design or make those lovely machines, cannot understand why girls should fail to play with them as enthusiastically, nine hours a day, for years. Yet why should they delight for ever merely in fiddling with bits and pieces, the function of which (often for necessary reasons) was unknown to them ? In peace-time, some of these girls would have been occupied, in sunshine and fresh air, with chickens, calves, even with their children. It is not recorded that they had been guided, by tests and psychological interviews, to different jobs, with some respect paid to their idiosyncrasies, as they would have been had they joined the Forces. Nor do we read of courses arranged by an Army Bureau of Current Affairs, or discussions in the British Way and Purpose. Yet incentive and motive are complex affairs, not easily to be packed into a pay-envelope.

The physical circumstances of the work seem to have been admirable. Though hours were long, the work was easy. There was good food, at which the amount of grumbling seems inversely related to the workers' degree of education and sophistication. Though some girls disliked being billeted upon inhospitable landladies, others were installed in an excellent hostel. But—and for the social psychologist this is perhaps the most interesting fact—in order that they might perform, as often as possible, a series of (to them) almost meaningless actions, everything else was done for them. They had no part nor lot in worries about food-rations or shopping; sometimes on returning home they found that their family had ceased to consult them even about important matters like taking a lodger. When the day's work was over, often they did nothing but have supper and go to bed. They seldom listened to the radio, or read a newspaper, and when an illustrated daily paper came their way, they thumbed it listlessly, chattering about astrology, fashions and dress coupons. When they gossiped it was usually not about others in the factory but about people at the real place : home. They regarded the War as something to be endured, like a very heavy shower of rain, which for some inscrutable reason has not stopped, cannot go on for ever and cannot be affected by their efforts. Even grumbles were seldom directed towards anyone who could remedy the fault.

Yet it should be remembered that for them there were no smart uniforms, presumably no badge to show that they were doing important war work, no glamour, no public parades. The town into which they were herded did not want them, showing this positively and negatively ; for example, when the firm suggested the establishment of a British Restaurant there was no effective local co-operation. For their sisters, the Armed Forces may have provided many things of which these workers were deprived, including a stimulation of the intellect and discussion of their future as citizens and voters. In the life of these young workers, there is a background of aimlessness, irresponsibility and boredom ; all regarded as inevitable. This study, in conjunction with other field-work, emphasizes the decline in positive citizenship among such young people. The *laisser-faire* of leisure and its dangerous separation from work are immediately and primarily responsible for this. Here, under its modern orchestration, the social psychologist's ear discerns an old, mournful tune.

T. H. PEAR.

RECOGNITION OF THE STARS

Star Recognition

By Ft.-Lieut. Francis Chichester. Pp. 20+3 charts. (London : George Allen and Unwin, Ltd., 1943.) 7*s*. 6*d*. net.

THIS book supplies a lot of useful information for those engaged in air-navigation star-work, and follows the procedure adopted in the "Air Almanac", dividing the stars into three Lots : Lot 1 contains 22 main stars which are printed in capitals; the 13 stars in Lot 2 are in italics, and Lot 3 contains 15 stars considered third class for air navigation; but Benetnasch and Polaris are now included among the 24 main air navigation stars, Polaris, though only second magnitude, being considered much more valuable to the navigator than any other stars. Very full directions are supplied for the identification of the stars in various quarters of the heavens, and some space is also devoted to a description of the appearances of the navigational planets, Venus, Mars, Jupiter and Saturn, and to the method for recognizing them. On a Mercator's projection 390 stars are charted, and these include all the first-magnitude stars, nearly all the second-magnitude stars, 247 third-magnitude stars, and 8 fourth-magnitude stars (Polaris cannot be shown on a Mercator's projection and hence does not appear on the chart). A duplicate projection on which the stars are not named provides a useful test for the identification of stars—first-magnitude especially—and will show the student his weakness in star recognition.

Identification of the stars by means of the Mercator star chart and also by computed declination and sidereal hour angle is described, and an example of the application of the former method is given. At the end of the work there is a "Catalogue of First Magnitude Stars, given in Order of their S.H.A., with their Mean Positions for January 1943 in Terms of Dec., S.H.A., and R.A., with Annual Variations for the Middle of the Year".

This is a most useful book for air navigators. With the star charts, which fold up, it is enclosed in a glazed linen folder.

Radio-Technology

By B. F. Weller. Pp. viii+358. (London : Chapman and Hall, Ltd., 1943.) 21*s.* net.

THE author of this book is a practical radio-engineer, who has had some experience in teaching the subject ; and he has endeavoured to provide an intermediate practical text-book suitable for students preparing for some of the recognized examinations in radio-communication. The reader is assumed to have a fundamental knowledge of electricity and magnetism, including the principles of alternating currents, and a mathematical ability normally associated with practical electrical engineering.

The scope of the work is approximately that of the terminal equipment—transmitters and receivers—required for radio-communication purposes. After an introductory chapter on alternating currents and resonant circuits, the general principles of the production of radio-frequency oscillations are described in Chapter 2. The properties of thermionic valves, from diodes to pentodes, are next dealt with, together with the circuit arrangements used for applying valves as rectifiers, amplifiers and oscillators.

This leads to a treatment of the principles of radio transmitters, and the keying and modulation methods used for telegraphy and telephony. Two chapters are then devoted to the general principles of reception, and the supersonic heterodyne type of receiver now so widely used for radio-communication purposes. A chapter on the various types of modern aerial systems and their relevant characteristics concludes the book.

The treatment throughout is descriptive of the technological principles of the subject without reference to any specific equipment, and should thus prove valuable to the practical operating and installation engineer who desires to acquire a closer fundamental knowledge of the branch of engineering in which he is engaged.

The Manure Note Book

A Handy Guide for Manure Manufacturers and Merchants, Farmers, Agricultural Students and Horticulturalists. By John Stewart Remington. Pp. v+58. (London: Leonard Hill, Ltd., 1943.) 3*s.* 6*d.*

THE first chapter of this book is devoted to a brief account of the constitution of soils and the composition of plants. Then follow two short chapters on the origin and use of farmyard manure and fertilizers supplying nitrogen. Chapter 4 is headed "Phosphatic Manures", but after a description of the commoner phosphatic fertilizers, gives an account of the origin, characteristics and uses of potash manures and lime, the residual effects of manures and the manurial requirements of some of the common crops. A short chapter on manures for fruit trees is followed by a collection of manure recipes for a wide range of agricultural and horticultural crops and a number of conversion tables, and tables of equivalence relating to materials used in the manufacture of fertilizers. The last fifteen pages of the book are devoted to tables showing the percentage of any nutrient in a fertilizer mixture from the weight of the fertilizer salt supplying that nutrient which is included in each ton of the mixture.

The manure recipes and the manurial requirements of crops are dealt with from the pre-war point of view. No reference is made to the present restrictions on the use of fertilizers or to some of the more modern fertilizers. Some of the fertilizer recommendations are not in agreement with the results of recent experimental work, and the inclusion of sulphate of potash in a special turnip and mangold manure while kainite is used in a potato manure seems difficult to justify. The book is likely to be appreciated more by the manure manufacturer than the farmer. F. H.

The Natural Development of the Child

A Guide for Parents, Teachers, Students and Others. By Dr. Agatha H. Bowley. Second edition. Pp. xvi+184+30 plates. (Edinburgh : E. and S. Livingstone, 1943.) 8*s.* 6*d.* net.

THE appearance of a second edition of this work, little more than a year after it was originally issued, is itself sufficient tribute to the way it has been received. Dr. Bowley set out to help parents and teachers who need guidance about the emotional development of children. To do this she has not only read widely—each chapter ends with a list of references—but also has arranged various investigations at the school psychological departments with which she has been connected. Having collected the material, the author has not impaired the value of her work by the inclusion of technical descriptions ; the book is intended for the non-specialist and in no part does it become too difficult for them. It is crammed with useful information for parents and teachers and, albeit inadvertently, shouts the need for more and more parents and teachers who are really fitted to guide young children towards maturity. "The Natural Development of the Child" continually raises the question as to whether the ability to produce a child is in itself sufficient justification for the parent to constitute himself or herself the most suitable guardian of the child. One also wonders if the ability to teach reading or writing or any of the 'ologies' should continue to be recognized as the main qualification required to help the child in its adjustment to life. T. H. H.

Map Reading and Avigation

An Introduction. By Richard M. Field and Harlan T. Stetson. Pp. xiii+129. (London: Chapman and Hall, Ltd., 1943.) 15*s.* net.

THE aim of this book is to provide an introduction to the subject for air cadets. The first half treats of map-reading from the point of view of the aviator, and is illustrated entirely from American maps, and even these, on account of censorship, have had to be chosen with discretion. The treatment is summary and omits some of the more familiar considerations generally embraced in the study of maps for surface travel. Particular attention is paid to the relation between aerial photographs, block diagrams and topographical surveys, and many well-devised exercises and problems are included. If space was a consideration, it is difficult to understand why a brief résumé of the physiographic region of the United States and Canada and a section on the moon should be included.

The second half of the book, and probably the most useful, is an introduction to air navigation for which the author uses a word of doubtful legitimacy, 'avigation'. This section is clear and lucid, and requires a minimum of mathematical skill. The relative merits of Mercator and the Lambert conformal projections are discussed. The diagrams are well drawn. A list of reference books and charts includes only United States publications. On the whole, it is a useful book and is admirably illustrated.

MEASURING THE DISTANCE OF THE SUN FROM THE EARTH*

By Sir HAROLD SPENCER JONES, F.R.S.
Astronomer Royal

THE distance of the sun from the earth or, speaking more correctly—for the distance is, of course, variable—the semi-major axis of the earth's orbit, is the most important constant in astronomy. It determines the scale not merely of the solar system but also of the whole universe. It enters into almost any calculation of distances and masses, of sizes and densities, either of planets or of their satellites or of the stars. Any error in its determination is multiplied and repeated in many different ways. The measurement of the sun's distance with the highest attainable accuracy is therefore of great importance in astronomy, and it is not surprising that vast amounts of time and labour have been devoted to it by astronomers in the course of centuries.

Many different methods are available for determining the sun's distance. They can be grouped into three main classes: geometrical methods, gravitational methods and methods involving the velocity of light. I shall deal primarily with the geometrical methods, those which depend upon direct measurement. But first I shall refer briefly to the other methods, which are indirect.

Gravitational Methods

The gravitational methods depend upon the fact that there is a theoretical relationship between the distance of the earth from the sun and the ratio of the mass of the earth to that of the sun. This relationship, which involves the length of the seconds pendulum and the length of the sidereal year, is known with great exactness; it is one of the best established results of celestial mechanics and is the principle on which the lunar theory is constructed.

Now the perturbing effect of the earth on the motion of a nearby planet, such as Mars or Venus, depends upon the ratio of the masses of the earth and the sun. If, then, by analysing the motion of the planet the perturbing effect of the earth is determined, we can infer the distance of the earth from the sun. But, on closer examination, it is found that the mass of the earth can not satisfactorily be determined from its action on the other planets, because the observations are affected by errors of a systematic nature, which it is impossible to control satisfactorily. When the errors of observation are of a purely random or accidental nature, increased precision in the quantity to be determined—in this case, the mass of the earth or the distance of the sun—can be obtained by increasing sufficiently the number of observations. But when, on the other hand, all the observations are affected in a similar way by a certain source of error, there is a limit to the precision attainable, and no increase in the number of observations will give a precision within this limit. The causes that limit the precision with which the mass of the earth can be derived from observations of Venus or Mars do not apply in the case of the minor planet Eros, which has an orbit of high eccentricity and a star-like image. The orbit of Eros has been determined with high accuracy and it is possible that the most accurate determination of the sun's distance will eventually be inferred from the mass of the earth derived from the perturbations produced by the earth in the motion of Eros. Time is on the side of this method, and as observations of the position of Eros accumulate the precision of the determination will increase.

Another gravitational method by which the mass of the earth and the distance of the sun can be derived is worth mentioning, because of its intrinsic interest. The orbits of the planets are subject to slow secular changes caused by the perturbing actions on each planet of the other planets. These secular changes can be deduced from the accumulated observations of the planets and compared with their theoretical expressions, which involve the masses of the planets; in this way the masses of the planets can be inferred. For many years a large and unexplained discordance in the motion of the perihelion of Mercury remained one of the outstanding problems of gravitational astronomy. This was at length satisfactorily accounted for by Einstein's generalized theory of relativity. But there was also another serious discordance: the mass of the earth derived in this way corresponded to a distance of the sun which was considerably greater than the distance derived by every other method. I have rediscussed these secular changes, introducing all the corrections required by the theory of relativity, and the discordance still remains. It arises almost entirely from a disagreement between the observed and theoretical motions of the node of the orbit of Venus. Observations of the transits of Venus and meridian observations of Venus show about the same discordance. This anomaly in the motion of the node of Venus has remained unaccounted for after the most exhaustive discussion. As the American astronomer, Simon Newcomb, said, "What adds to the embarrassment and prevents us from wholly discarding the suspicion that some disturbing cause has acted on the motion of Venus, or that some theoretical error has crept into the work, is that, of all the determinations of the Sun's distance, this is the one which seems the most free from doubt arising from possible undiscovered sources of error". Again, "Unknown actions and possible defects of theory aside, it seems to me that the value of the Sun's distance derived from this discussion is less open to doubt from any known cause than any determination that can be made". Yet determinations of the sun's distance by every other method suggest that the distance obtained in this way is seriously in error.

A third gravitational method is based on the determination of an inequality in the motion of the moon known as the parallactic inequality. The disturbing action of the sun on the moon is greater at new moon than at full moon because the moon is nearer the sun when new than when full. In consequence the time of first quarter is slightly retarded and that of last quarter is slightly accelerated. The parallactic inequality involves the sun's distance, and this can therefore be inferred when the parallactic inequality is determined from the analysis of the moon's motion. The determination of this inequality from meridian observations of the moon is peculiarly liable to systematic error, because observations have to be made on one limb of the moon when the inequality is positive and on the other limb when it is negative; any error in the adopted semi-diameter of the moon therefore enters almost to its full amount into the derived value of the inequality. It is better to use observations of occultations of stars by the moon. Near first quarter the stars dis-

* Royal Institution discourse delivered on January 28.

appear, as the moon moves eastwards relative to the stars, at the dark limb of the moon; these disappearances can be accurately observed. The stars reappear at the bright limb and, because they are likely to be lost in the glare of the moon at the instant of reappearance, the time of reappearance is almost certain to be late. Near last quarter, the stars disappear at the bright limb and may be lost in the limb glare before the instant of true occultation, so that the observed time of disappearance is likely to be early. They reappear at the dark limb and the instant of reappearance should be accurately observed, provided the observer is looking at the right spot. The systematic errors which may thus be introduced can be controlled by discarding observations at the bright limbs, except those of stars sufficiently bright to be seen readily at the limb. With proper precautions, a good determination of the sun's distance can be made from observations of occultations.

Velocity of Light

Of the methods involving the velocity of light the first is of historical interest only. In 1675 Römer had proved that light does not travel instantaneously, but with finite velocity. He found that the eclipses of Jupiter's satellites occurred later than they should when the earth was on the far side of its orbit from Jupiter, and earlier when the earth was on the near side of its orbit. The extreme difference in time, amounting to about 16½ minutes, represents the time required by light to travel across the diameter of the earth's orbit. As the velocity of light is now known with high precision, the distance of the sun can be inferred from observations of the times of eclipses of Jupiter's satellites. But this method does not permit of high accuracy.

A better method is provided by the phenomenon of aberration, discovered by James Bradley in 1728. Bradley had been puzzled by certain anomalies in his measurements of the positions of stars. The stars seemed to be pushed slightly out of their places, always towards the direction of the earth's motion. Bradley puzzled for a long time about the cause of these displacements; but at length he correctly explained them as due to the finite velocity of light. The direction in which a star is seen depends upon the motion of the earth and the finite speed of travel of light, and as the earth travels round its orbit in the course of a year, a star appears to describe a small ellipse in the sky. The displacements in the positions of the stars depend upon the ratio of the speeds with which the earth and light travel. This ratio is called the constant of aberration, and there are many ways in which it can be determined by astronomical observations. The velocity of light being known, the constant of aberration determines the speed of the earth. But the speed of the earth is related to the size of its orbit, for its orbital path is described in one year and, the speed being known, the size of the orbit and, consequently, the distance of the sun can be inferred.

It might be thought, therefore, that from the many determinations of the aberration of the stars, the distance of the sun could be found with very high precision. But the method proves to be attended with serious difficulties. The measurement of aberration depends essentially on the comparison of the apparent positions of stars obtained at intervals of about six months, when the earth is at opposite ends of its orbit. Moreover, the observations at one season must be made soon after sunset and at the other season shortly before sunrise. Thus all sorts of troublesome errors of a systematic nature, involved in seasonal and diurnal changes, are liable to enter. The errors bound up with seasonal climatic variations are among the most troublesome in astronomy, and it is practically impossible to eliminate them. For this reason it is preferable not to use the constant of aberration as a means of inferring the sun's distance, but to use the sun's distance, determined by other methods, to infer the constant of aberration.

Of the methods for finding the sun's distance that involve the velocity of light, the most promising is based on the measurement of the exact positions of the lines in the spectra of selected bright stars near the ecliptic. The motion of the earth towards or from a star alters the wave-lengths of the spectral lines, causing them to shift slightly to and fro. The shifts in the wave-lengths of the lines depend upon the velocity of the earth towards or away from the star. This again leads to a determination of the sun's distance. Some observations at the Cape by this method gave promising results, but long-continued observations on a number of bright stars, using a very large telescope and a spectrograph of high dispersion, are required in order to obtain an accurate result. The many demands on the observing time of powerful telescopes have prevented the method being given an adequate trial. A difficulty of the method is that any changes in the motion of the star itself—such as orbital motion or pulsations in its atmosphere—also give rise to displacements in the positions of its spectral lines and, unless these can be allowed for or are of a random nature, the accuracy of the result will be impaired. It is also necessary to take careful precautions that no displacements of instrumental origin, such as might be caused by instrumental flexure, can occur.

Direct Observation Methods

We come now to the determination of the sun's distance by direct observation. This type of method depends upon the measurements of angles. The process is essentially the same as that used by a surveyor in the measurement of the earth's surface by triangulation. He starts with an accurately measured base-line and determines the distance of a far point by measuring, from each end of the base-line in turn, the angle between the base-line and the direction to the far point. This enables him to calculate the distance of the point from each end of his base-line. In the case of the sun, the angle to be measured is what is called the horizontal parallax of the sun—or, more briefly, the solar parallax; it is the amount by which the sun at rising or setting is apparently moved—to an observer on the rotating earth—from its true place in the heavens. This angle of parallax (about 8·8″) is the angle subtended by the radius of the earth as seen from the sun. It is about equal to the diameter of a halfpenny as seen 2,000 ft. away. It will be understood that to determine this small angle with an accuracy of about one part in ten thousand is far from an easy matter.

The sun is a difficult object for accurate measurement under the best conditions; its large size and the effect of its heat on the instruments used limit the accuracy of the measurement. If the distance of the sun could not be determined otherwise than by direct observation of the sun, it would be a vain hope to expect an accurate answer. But, fortunately, this is not necessary. The laws governing the motions

of the planets which were enunciated by Kepler in the year 1618 enable the relative distances of the planets in the solar system to be inferred with very great accuracy from the periodic times in which their orbits are described. The solar system can therefore be accurately drawn to plan; the scale of the plan is fixed when any one distance in it has been measured. The smaller the distance, the more favourable are the circumstances for accurate measurement, because the angle of parallax—from which the distance is inferred—is larger in relation to the errors of observation. From time to time, one or other of the planets in their unending journey round the sun comes sufficiently near the earth to enable the sun's distance to be measured with reasonable accuracy. The two planets which appeared to offer the best scope for measuring the sun's distance by direct observation were Mars and Venus. Venus comes closer to the earth than Mars does; its nearest distance is about 26 million miles, whereas Mars, when nearest, is 34½ million miles away. But Venus, when at its nearest, is between us and the sun. It then becomes lost to sight in the rays of the sun and it is only on the somewhat rare occasions when its path lies directly in front of the sun and it can be seen to transit across the sun's disk that measurements become possible. Four transits of Venus occur every 243 years, at successive intervals of 8, 105½, 8 and 121½ years. Five transits only have ever been observed, namely, the transits of December 4, 1639; June 6, 1761; June 3, 1769; December 9, 1874; and December 6, 1882. The next two will occur on June 8, 2004, and June 6, 2012. It was Halley who first suggested in 1679 that the transits of Venus would provide favourable opportunities for determining the sun's distance.

But the first scientific estimate of the distance of the sun was made from observations of Mars. The orbit of Mars is more elliptical than the orbit of the earth, so that the distance of Mars from the earth when in opposition, that is, with the earth directly between Mars and the sun, can range from 34½ million to 63 million miles. The favourable oppositions, when the distance is least, occur at intervals of fifteen or seventeen years, in August. Mars, when in opposition, crosses the meridian at midnight and is suitably placed for observation. A favourable opposition occurred in 1672. Observations to determine the sun's distance were planned by Giovanni Domenico Cassini, the first director of the Paris Observatory, then just completed. He sent an expedition to Cayenne to make observations of Mars, while corresponding observations were made at the Paris Observatory. Paris and Cayenne thus formed the ends of a base-line, and from the difference in the direction of Mars as seen from the two places the distance was to be inferred. The result of the observations was to place the sun at a distance of between 82 and 91 million miles, with a probable value of 86 million miles—a value that was accepted for about a century.

The determination of the distance of the sun by observations of Mars in this manner is liable to a very serious systematic error. At each station the position of Mars in the sky is determined with reference to adjacent stars. The effect of parallax is to displace Mars away from the zenith. Atmospheric refraction, on the other hand, displaces it towards the zenith; but as it displaces the stars also towards the zenith, its effects would be eliminated if Mars and the stars were refracted by the same amount. Refraction, however, is greater for blue than for red light, because of the dispersive power of the atmosphere. Because Mars is redder than the average star, it is displaced by refraction towards the zenith by an amount that is smaller than the average amount by which the adjacent stars are displaced. Hence, as compared with the stars, Mars will be effectively displaced away from the zenith. This differential displacement, caused by atmospheric dispersion, will be interpreted as the effect of parallax. The measured parallactic displacement will therefore be too great, and too large a value of the solar parallax, corresponding to too small a distance of the sun, will be inferred. The distance found in 1672 was, in fact, appreciably too small.

In 1877, Gill made an expedition to the Island of Ascension to make observations of Mars at a favourable opposition in order to determine the solar parallax by a method which Airy, the Astronomer Royal, had recommended. Its principle consists in substituting successive morning and evening observations from the same spot for simultaneous observations from two different spots, the rotation of the earth supplying the necessary difference in the points of view. Gill made his observations with an instrument termed a heliometer, which has an objective divided into two halves along a diameter. The two halves can be displaced relatively to one another, enabling the images of two objects, for example, Mars and a star, formed by the two halves separately, to be brought into coincidence. An accurate measure of the angular distance between the two objects can be inferred from the separation of the two halves of the objective required to give coincidence. Gill obtained a low value for the solar parallax, 8·78″, instead of the high value that would be expected. Newcomb, in collating various determinations of the solar parallax, rejected all those based on observations of Mars, with the exception of Gill's. He remarked: "It may be objected that it should be rejected for the same reason, since the colour of the planet would affect heliometer observations and meridian observations equally. I have, however, considered it free from the objections in question for two reasons. In the first place, the result is not too large, but is, on the contrary, the smallest of all the accurate measures. The principle that when a result is open to a strong suspicion of being affected by a cause which would cause it to deviate in one direction, it is logical to conclude *a posteriori* that the cause has not acted if the deviation is found to be in the other direction, may not be a perfectly sound one, but I have nevertheless acted upon it".

The explanation of Gill's low value of the parallax was not found until 1924 and is of some interest, as illustrating how systematic errors can enter into such observations and lead to erroneous results. In 1924 there was another favourable opposition of Mars, and I arranged a programme of observations at the Cape, which was shared by three observers, Dr. Halm, Mr. Wilkin and myself. These observations gave again a low value of the solar parallax, 8·76″, even lower than Gill's value. The same value was obtained from the observations of distances, position angles or right ascensions, so that the observations were internally consistent. When, however, the observations were grouped according to the observers, surprisingly large differences were obtained:

Halm	.. ..	8·70″ ± 0·02″
Jones	.. ..	8·77 ± 0·02
Wilkin	.. ..	8·81 ± 0·02

The differences were much greater than the probable errors. Such a result had not been expected, because adequate precautions had been taken to guard against errors of 'personality'.

Now there was one, and only one, point on which the observers had differed. With the heliometer a series of graded wire-mesh screens are used, which can be placed at will over either half of the objective, so as to reduce the brightness of the object viewed. It was left to the judgment of each observer which screen should be used under any particular conditions of observation. Halm used the densest screen, even in cases where measurement would be possible with a more open one; Wilkin showed great reluctance in using the dense screen, while I adopted an intermediate attitude, using the less dense screens for preference, but falling back on the densest screen whenever observations became at all difficult with the other screens. The presumption that the use of the densest screen gave the lowest value of the solar parallax could be checked in two ways: (*a*) under conditions of bad seeing, the image of a star becomes weak and diffused instead of appearing as a bright point of light, and it is then lost against the bright disk of Mars unless the densest screen is used to reduce sufficiently the brightness of Mars; thus we may expect a smaller value of the solar parallax to result from the nights of bad seeing than from the nights of good seeing; (*b*) for similar reasons, the densest screen had to be used more frequently when observing faint stars than when observing bright stars, so that again we may expect to find a smaller value of the parallax from observations of faint stars than from observations of bright stars. These expectations were confirmed and in each case the zenithal displacements required to account for the observed discrepancies were calculated. The results were as follows:

	Zenithal displacement		Difference in
	From R.A.	From Dec.	solar parallax
Jones—mean . ..	+0·02″	+0·04″	+0·01″
Halm— ,, ...	−0·13	−0·14	−0·06
Wilkin— ,, ...	+0·10	+0·10	+0·05
Bad—good seeing .	−0·15	−0·16	−0·08
Faint—bright stars .	−0·13	−0·12	−0·05

The agreement in each case in the zenithal displacements deduced from right ascensions and declinations separately demonstrates conclusively that the phenomenon has its maximum effect in the direction towards or from the zenith. Now it is a well-known fact that the sensibility of the human eye for colour depends on the intensity of the light source. The more the intensity of the light of Mars is diminished, the more sensitive does the observer become to the blue portion and the less sensitive to the red portion of its spectrum. With the densest screen the ruddy appearance of the planet was, in fact, completely lost. The conclusion is that the screens used for reducing the light of the planet show a tendency to enhance the susceptibility of the observer for the more refrangible portion of the planet's light and consequently displace the apparent disk towards the zenith as the result of atmospheric dispersion. Thus when observing with the heliometer, there is a tendency for too small a value of the solar parallax to be given by observations of Mars, contrary to what might have been expected.

Transits of Venus

Of all the methods of determining the solar parallax, the observation of the transits of Venus is the one that has raised the highest hopes, that has involved the largest expenditure of energy and resources and has proved the greatest failure. As viewed from remote parts of the earth, the track of Venus across the disk of the sun will be different, and the times of beginning and ending the transits will be different. The differences of path or of time can be translated into differences of space, and the distance of Venus and hence of the sun inferred. As Halley said, when emphasizing the advantages of the method, the times of beginning or ending the transit could be determined with accuracy "without any other instruments than telescopes and good common clocks, and without any other qualifications in the observer than fidelity and diligence, with a little skill in astronomy". So the astronomers of the eighteenth century were full of hope and of zeal as the two transits of 1761 and 1769 drew near. The principal Governments of Europe fitted out expeditions to various parts of the world, observers being scattered to many stations over the face of the earth. It is worthy of note that it was the transit of 1769 that gave Captain Cook his chance to establish his fame as a navigator. He took a party of observers in the *Endeavour* to Tahiti in the South Seas and, after the transit had been observed, completed his three-year voyage round the world. Mention may also be made of the ill fortune that befell the French astronomer Le Gentil. He had intended to observe the transit of 1761 at Pondicherry, but the war between the French and the English caused him to arrive too late. He decided to remain there for eight years to make certain of observing the transit of 1769, but clouds at the critical time prevented him from seeing anything. On his eventual return to France, he found that during his long absence he had been adjudged legally dead and all his property had been divided amongst his next-of-kin!

The results of these observations were disappointing in the extreme. Unexpected difficulties were encountered in determining the exact instants of contact between the dark disk of Venus and the bright disk of the sun. Instead of meeting and parting with a clean definiteness that had been looked for, they appeared to cling together, a black spot seeming to form between the edge of Venus and the edge of the sun, somewhat as a drop of ink clings to a pen which is slowly withdrawn from an inkpot. The results obtained by the various expeditions were very different and discordant, and the uncertainty in the sun's distance remained at several millions of miles.

As the transits of 1874 and 1882 approached, it was confidently expected that they would give a final answer to the question of the sun's distance. It was believed that the difficulties experienced in 1761 and 1769 would yield to the skill of forewarned preparations. More than a century had passed and not in vain. There had been during that time many improvements in instruments, in methods of observation and in technique. Photography was being developed as an aid to the astronomer and much was hoped from it; though there might be difficulty in co-ordinating and interpreting visual observations, the camera could not lie and would be free from bias. The camera and the heliometers would both enable the position of the dark body of Venus seen against the bright background of the sun to be accurately determined, free from any peculiar phenomena, at the contacts. So the most intensive scheme of international co-operation that astronomy had yet seen was organized well in advance. Official commissions were appointed to consider the best methods of observations. Models

were constructed to train the observers and to determine their personal equations. Special instruments were made to ensure uniformity in equipment and method. Great Britain, France, Germany, Italy, Russia, Holland and the United States co-operated and some four score stations were occupied, at a cost of nearly a quarter of a million pounds. Siberia, the Sandwich Islands, Kerguelen and the almost inaccessible St. Paul's and Campbell Islands were among the places to which expeditions were sent. The weather proved generally favourable; the well-organized arrangements proved equal to the test; the contacts were well observed and many photographs were obtained.

Yet the results proved a great disappointment. The 'black drop' again gave trouble, but not more than was expected. More troublesome was the illumination due to the atmosphere of Venus, which caused the planet to be illuminated with a ring of light; its power to mar observations by the distorting effect of refraction had not been foreseen. So uncertain were the instants of precise contact that observers, with identical equipment, and standing a few feet from one another, recorded times that differed by as much as a minute. Photography, on which such high hopes had been based, proved an almost total failure. The great campaign left the distance of the sun uncertain by about $1\frac{1}{2}$ million miles.

Chastened but undaunted, preparations for the second transit were pushed ahead, in the hope that benefits could be obtained from the experience gained in 1874. Some countries withdrew on the ground that other methods of finding the sun's distance were more accurate and less costly. The arrangement of the observations was discussed by an international conference in Paris in 1881. Again there were many expeditions, the British parties being scattered from Queensland to Bermuda: visual and photographic observations were once more tried. The results were once more disappointing; the distance of the sun came out at $92\frac{1}{2}$ million miles, but the diversity of results given by the different expeditions and by different methods of discussion showed that no great confidence could be placed in this value.

The Asteroids

But meanwhile other objects more suitable for observation than Mars or Venus had come within the range of celestial trigonometry. In the wide gap between the orbits of Mars and Jupiter there exists a swarm of tiny planets or asteroids circling round the sun. The first to be discovered was found on the night of January 1, 1801, by the Sicilian astronomer, Piazzi, and was named by him Ceres, after the tutelary deity of the island. About a couple of thousand of these small bodies are now known. Most of the asteroids are of little intrinsic interest, and the somewhat monotonous work of keeping track of them is carried on because from time to time one of them proves to be of special interest. In 1872, it was suggested by Galle that some of the asteroids might repay astronomers for much of their disinterested toil in keeping track of them, by aiding their efforts to determine the scale of the solar system. Some of them are sufficiently bright and come near enough to be of use for this purpose and, being small enough to appear like a star in the telescope, they have a distinct advantage over Mars or Venus, with their large disks. In 1888 and 1889, from observations of the three asteroids, Victoria, Iris and Sappho, Gill obtained a solar distance of 92,874,000 miles—undoubtedly the most accurate determination that had been made up to that time.

The 433rd asteroid to be discovered, found on August 14, 1898, and named Eros, proved to be of singular importance for measuring the sun's distance. It is a small body, only some 15 miles in diameter, with an orbit so elliptical that from time to time it comes within about 15 million miles of the earth. One such near approach had occurred in 1894, shortly before its discovery. Since then its nearest approaches have been in 1901, when its least distance was somewhat less than 30 million miles, and in 1931, when its least distance was only 16,200,000 miles, affording the most favourable opportunity that has ever occurred for determining the sun's distance. Extensive observations of Eros were obtained in 1901. But the observations were far more numerous in 1931; the circumstances were far more favourable at the latter date, and the great advances made during the present century in the applications of photography to precise astronomical measurements enabled greater accuracy to be obtained in the more recent observations. The results from the 1931 observations will therefore alone be referred to.

Observations of Eros in 1931

The observations were almost entirely photographic; the method used was to photograph Eros and the surrounding stars on the same plate and then, by careful measurement, to determine the exact position of Eros among the stars. A base-line can be obtained by using two different observatories and combining the observations to give the relative displacement of Eros as seen from the two ends of the base-line; or the base-line can be provided by the rotation of the earth, the observations at the same observatory in the evening and the following morning being combined. During the interval between the observations, both the earth and Eros have moved somewhat along their orbits round the sun. The displacement during this interval in the position of Eros as seen from the earth must be allowed for. This is not a matter of great difficulty when the paths of Eros and the earth round the sun are accurately known. Now it is usually stated that the path of a planet round the sun is an ellipse. This would be so if there were no other planets. But gravitation is a universal force. It is the gravitational pull of the sun that compels the earth to travel round the sun; but all the while each of the other planets of the solar system is also exerting a gravitational pull on the earth, which depends on the mutual distance between the earth and the planet, and the pull is continuously changing as the earth and the planet move. The effects of the gradually varying pulls of the other planets on the earth and on Eros must be determined and taken into account when calculating the paths of the earth and of Eros. This is a long and intricate task, which was undertaken by Dr. Witt, the discoverer of Eros.

As the positions of Eros had to be derived by reference to adjacent stars, it was necessary to determine specially the positions of a sufficient number of stars for this purpose. A selection of 900 stars, bright enough to observe with meridian instruments and lying in a narrow belt extending 1° on either side of the path of Eros, was made. These stars were sufficient in number to average ten or twelve on a plate, centred at any point on the path of Eros and covering the field of $2° \times 2°$, obtainable with instru-

ments having a focal length up to about 12 ft. Their positions were determined at thirteen different observatories and combined into a definitive catalogue on a homogeneous system at the Rechen Institut, Berlin. But photographs with modern long-focus instruments cover a much smaller field, and the primary reference stars were too few in number to enable the positions of Eros to be derived from these photographs. A selection of some 6,000 fainter secondary reference stars was therefore made, the positions of which were obtained by photographic methods, using the primary stars as reference points. Special series of photographs were obtained for this purpose at the Greenwich, Bergedorf, Leipzig and Cape Observatories and combined into a definitive catalogue at Greenwich.

The path of Eros during the time when its parallax was large enough for observations to be worth while was in the form of a large arc across the sky, from north to south. It was at first only observable at northern observatories, but as it moved rapidly southwards it came within range of southern observatories, and eventually passed out of range of most of the northern observatories. Observations were obtained at some three dozen observatories, scattered over the world in all five continents. But the visual observations proved to be considerably inferior in accuracy to the photographic, and the derivation of the solar parallax was eventually based on photographic observations with thirty telescopes at twenty-four observatories in England, the U.S.S.R., Germany, Belgium, Czechoslovakia, Italy, Spain, Algiers, the United States, China, Japan, South Africa, Australia and the Argentine. 2,847 plates were measured and used.

The solar parallax can be derived from the observations in several ways. First, using the diurnal method, each instrument with which observations on several nights with a sufficient range in parallactic displacement were obtained will give a determination. Sixteen separate determinations were thus obtained, as shown in Table 1. The relative weights are based on the probable error of each determination. The weighted mean value is 8·7900″ ± 0·0013″.

TABLE 1. SOLAR PARALLAX: SEPARATE DETERMINATIONS FROM RIGHT ASCENSIONS.

Instrument	Parallax and p.e.	Relative weight
Cape 13-in.	8·7886″ ± 0·00165″	36·7
Cape 24-in.	8·7902 ± 0·00175	32·6

Dearborn	8·8070 ± 0·0061	2·7
Zô-Sè	8·7868 ± 0·0049	4·2
Union Obs.	8·7918 ± 0·0074	1·8
Lick	8 7887 ± 0·0080	1·6
Melbourne	8·7949 ± 0·0082	1·5
Greenwich 13-in.	8·7648 ± 0·0078	1·6
Greenwich 26-in.	8·7820 ± 0·0115	0·8
McCormick	8·7861 ± 0·0091	1·2
Washington	8·8160 ± 0·0101	1·0
Tokyo	8·7459 ± 0·0183	0·3
Catania	8·7865 ± 0·0336	0·1

The internal consistency of the results can be examined by subdividing the material in different ways. First, the three series with preponderating weight, on which the combined weighted mean value will largely depend, can be separated from the other thirteen series and the separate mean values compared. Secondly, those determinations based on primary star places can be compared with those based on secondary star places, to see whether there is any systematic effect connected with the brightness of the comparison stars. Thirdly, the results obtained with instruments designed for photographic observations can be compared with those obtained with visual instruments, used photographically by employing yellow sensitive plates and yellow filters. In each case there is a satisfactory accordance.

The results derived in this way are independent of systematic corrections required by individual instruments, but a considerable wastage of material is involved. Not only are unbalanced observations excluded (that is, where evening or morning observations, but not both, have been obtained), but also observations with other instruments the series of which were not sufficiently complete, have not been used at all. New solutions were therefore made, night by night, using all available material. 129 separate determinations of the solar parallax were thus obtained, with the weighted mean value 8·7875″ ± 0·0009″. The internal consistency was checked by dividing it into four groups of approximately equal weights; these gave values in close accordance.

An entirely independent determination of the parallax can be made by comparing observations at a northern and a southern observatory, the base-line being provided by the line joining the two observatories. This method uses observations in declination, instead of in right ascension. The results of a series of separate determinations are given in Table 2. The results are not entirely independent, because some of the material is used several times over, but they show the general consistency. Individual determinations were therefore made for each night on which sufficient observations at one or more northern and one or more southern observatories were obtained. Seventy-one separate determinations were thus made, giving a mean result of 8·7907″ ± 0·0011″. Dividing the material into three groups, concordant results were again obtained.

TABLE 2. SOLAR PARALLAX: SEPARATE DETERMINATIONS: N–S COMPARISONS

Lick; Cordoba	8·7909 ± 0·0086	9

Thus, summing up, the final results for the solar parallax from the Eros observations are:

R. A. Observations.

(*a*) Mean value from sixteen separate determinations, 8·7900″ ± 0·0013″.

(*b*) Value from all observations combined, 8·7875″ ± 0·0009″.

Dec. Observations.

(*c*) Value from all observations combined, 8·7907″ ± 0·0011″.

The three determinations are adequately represented by a value of the solar parallax of

8·790″ ± 0·001″;

corresponding to the sun's distance:

93,005,000 ± 9,000 miles.

The assigned probable error is based on the internal accordance of the observations. It is so small that the sun's distance is derived with an exactness adequate for all purposes unless there is some systematic error affecting all the observations. A possible source of such error is differential atmospheric dispersion, if the colour of Eros differs from

the colour of the average star. We have already seen that such errors can be considerable in the case of Mars. A very careful and detailed investigation into this possibility has been made. We have seen that if Eros is redder than the average of the comparison stars, we may expect to obtain too large a value of the solar parallax. Now a number of determinations of the colour of Eros were made, and it was found that it was slightly, but only very slightly, redder than the average of the comparison stars. Thus, on this showing, we might expect our concluded value of the solar parallax to be a little too large.

But the matter is not quite so simple as that. All the observations were made with refracting telescopes, in which the light is collected by lenses; none of them was made with a reflector. The aberrations of lens systems play a not unimportant part in modifying our conclusions, which are strictly applicable only to a perfectly achromatic instrument, in conjunction with a photographic emulsion equally sensitive to all colours. Thus, for example, to consider but one way in which the conclusions are modified: if a refractor of the normal astrographic type is focused to give the sharpest images at its centre then, at the edge of the plate, the rays that are brought to a sharp focus are not those which are photographically most effective, but rays of a somewhat greater wave-length. If, in measures of colour, there are two stars of the same colour, one at the centre of the plate, the other at the edge, the latter will appear the redder. Now, because Eros is always photographed at the centre of the plate, this effect will counteract in whole or in part the small difference in colour between Eros and the comparison stars. There are many other factors concerned, but the outcome of the discussion is that, with so many different instruments employed, what at first sight appeared to be a troublesome systematic error tends to assume a random nature. In so far as any residual systematic effect remains, it should be revealed by a correlation between the determined values of the solar parallax night by night and the distance of Eros; for the atmospheric dispersion effects are independent of the distance of Eros, whereas the parallactic displacements are greater the nearer Eros is to the earth. An investigation of the correlation between the solar parallax and the distance of Eros was made for both the right ascension and the declination observations. The deduced effects, which were comparable with their probable errors in each case, were of opposite sign in the two co-ordinates. The conclusion is that the general effects arising from colour differences between Eros and the comparison stars are negligibly small. This is a fortunate circumstance, and one that could not have been foreseen. The conclusion is corroborated by the agreement, within the limits of their probable errors, between the mean values of the solar parallax derived from photographic and visual instruments. Colour effects with the visual instruments are only two-fifths as great as with the photographic instruments; the concordance of the results from the two types shows that the effects are negligible.

One hundred years ago the distance of the sun was uncertain to one part in twenty; gradually, the uncertainty was narrowed to one part in a hundred, and then to one part in a thousand; now it has been reduced to one part in ten thousand. In 1858, Sir John Herschel, referring to a new determination of the sun's distance, which had brought the sun nearer by 4 million miles, wrote: "The superficial reader (one of a class too numerous) may think it strange and discreditable to science to have erred by nearly 4 million miles in estimating the Sun's distance. But such may be reminded that the error in the Sun's parallax, on which the correction turns, corresponds to the apparent breadth of a human hair at 125 feet, or of a sovereign at 8 miles off". The uncertainty in our latest determination corresponds to the apparent breadth of a human hair at 10 miles, or of a halfpenny at 3,250 miles! Looked at in another way, a similar accuracy in measurement of the distance of the moon would set the moon only 100 yards nearer to or further from us than it really is.

The goal for which astronomers have so long been striving has at length been reached. The final word has been said on this historic problem for many years to come, and the fundamental distance in astronomy has been measured with all the accuracy that is needed.

THE RAPID TREATMENT OF SYPHILIS

By Major JAMES MARSHALL, R.A.M.C.

RESEARCH into the problem of producing a safe and rapid method for the cure of syphilis has been given an added impetus during the war period, not only by an increase in the incidence of the disease, but also by the necessity for rapid rehabilitation of men who must be fit to move quickly and keep fit in conditions where continuous treatment may be impossible. The following account traces the evolution of the arsenical treatment of syphilis with special reference to intensive or massive arsenotherapy.

When Ehrlich, in September 1909, presented to Prof. Alt, for clinical trial, his preparation 'Ehrlich-Hata 606' he believed that he had discovered an immediately effective single-dose cure for syphilis. A year later Ehrlich, a little shaken, claimed that "606" in the original dosage was curative in 90 per cent of cases of syphilis. An accumulation of evidence in the form of relapsed cases soon showed, however, that the early high hopes could no longer be entertained. It is probable that a certain small percentage of cases of early syphilis are cured by one injection of "606"; but the difficulty of assessing cure makes the relative over-treatment of every case necessary in order to cover every eventuality.

In 1916 Pollitzer evolved a rapid treatment for early syphilis by three or four daily injections of arsphenamine, but here again early relapses proved the inadequacy of the scheme, and long-term investigation has shown that the end results of such treatment are very poor. Other like methods for the abortive treatment of early cases were found in time to be equally uncertain.

It finally became evident that the best prospect of cure was to be found in a treatment where a drug of the arsphenamine series was administered at the same time as a heavy metal preparation. Bismuth was found to be superior to mercury, and for the last twenty years has been the heavy metal of choice.

This combined scheme has proved highly successful and has stood the test of time, the most important test in the estimation of cure in syphilis. The great drawback is that, to be certain of effecting a cure, the patient must remain constantly under treatment for at least a year and sometimes longer. In principle

the present-day British scheme in common use for cases of early syphilis aims at administering about forty injections of a drug of the arsphenamine series and the same number of injections of a bismuth preparation over a period of about one year (standard scheme). The number of injections and time of treatment is increased in some cases, but is rarely reduced. The spacing and arrangement of treatment varies, naturally, in different hands, and a variety of arsenicals is in use. Neoarsphenamine is still generally used in Britain, but arsenoxide is beginning to become more popular.

Arsenoxide, known to, but discarded by, Erhlich, is not an arsphenamine, and does not need to be broken down in the body to become spirochæticidal. It is rapidly excreted, and, in the opinion of many venereologists, must be injected at least twice weekly to achieve results comparable with those obtained with single weekly injections of an arsphenamine. If arsenoxide is used on the standard treatment scheme, the number of visits by a patient to doctor or clinic is doubled, and the rate of default from treatment rises accordingly. Arsenoxide has many advantages in other directions and these will be discussed later. It is believed by some American authorities to be, in proper dosage, the equal of '606', which has not yet been surpassed as a spirochæticidal agent. Some arsenoxide preparations for injection are known as 'Mapharside' or 'Mapharsen', 'Neohalarsine', and 'Chlorarsen'. Of these 'Mapharside' is the preparation which has so far been most used in intensive treatments.

Although the progress in cases of early syphilis treated by the standard scheme is very good (approaching 100 per cent cures) if treatment is faithfully followed, well under 50 per cent of patients, by reason of default, receive enough treatment to ensure a cure-rate of more than 80 per cent.

It is obvious, therefore, that any method which will give a high rate of cure in a short time will be of the greatest value to the patient and to the State.

No real approach to the rapid treatment of syphilis was made until it was shown by Hirshfeld, Hyman and Wanger that 'speed shock' following injection could be avoided by slow intravenous drip. By slow injection at a rate of 2 or 3 c.c. per minute, toxic substances could safely be introduced into animals in doses much greater than by a rapid method.

The first application of this discovery was made in 1934 at the Mount Sinai Hospital in New York City, when a number of patients with early syphilis were given 4 gm. or later 5 gm. of neoarsphenamine by a continuous intravenous drip over a period of five days. Results were very good.

Later a similar scheme was instituted in which 'Mapharside' was substituted for neoarsphenamine. The optimum dose of 'Mapharside' was discovered, by trial and error, to be 1,200 mgm. given at the rate of 240 mgm. a day, in 2,400 c.c. of 5 per cent dextrose solution. The results with 'Mapharside' were also very good, and severe toxic reactions, a grave drawback with neoarsphenamine, were much reduced. Neoarsphenamine is not now used in intensive treatment. A modification of this five-day scheme is the administration of 'Mapharside' in divided doses by syringe at intervals throughout the days.

About 85 per cent of cases treated with neoarsphenamine and 82 per cent of those treated with 'Mapharside' were clinically and serologically well after periods of from six months to six years.

Since these original experiments a number of other intensive methods of treatment have been tried in early syphilis, ranging in duration from one day to thirty days of arsenical treatment. The arsenical used has been arsenoxide, usually 'Mapharside', and in some schemes bismuth has also been used. One of the most promising schemes involves one daily injection of arsenoxide for twenty days, to give a total dosage of 1,200–1,800 mgm. of 'Mapharside'.

The most important complication of intensive arsenotherapy is hæmorrhagic encephalitis, and the higher the dosage of arsenic the more likely appears to be the risk. Some investigators have attempted to achieve good results on small doses (less than 1,200 mgm.) of arsenoxide by combining fever therapy with arsenotherapy. In one such investigation, fever was induced by intravenous injection of typhoid vaccines four times in a treatment period of eight days. The most widely publicized combined fever and arsenic treatment is the one-day scheme in which 'Mapharside' is administered in the course of a ten-hour session of high fever (hyperthermy) at 106° F. It is still much too early to judge the results of this form of treatment. A premature account of this method by Paul de Kruif in the *Readers Digest* of September 1942 caused a great deal of confusion and unfounded dissatisfaction in the lay mind. The enormous circulation of the *Readers Digest* gave medical men in America, and also in Britain to a smaller extent, a good deal of extra work to explain just why every case of syphilis could not be cured in one day.

All intensive treatment for early syphilis must still be considered as being experimental, because enough time has not yet elapsed to exclude all possibility of late relapse in the patients so far treated. Only in the earliest series is it possible to hazard a reasonably accurate estimate of the cure-rate.

Hæmorrhagic encephalitis gives a fatality-rate of 1 in 111 in the five-day treatment with neoarsphenamine and 1 in 300 in the five-day treatment with 'Mapharside'. The fatality-rate with 'Mapharside' is at least four times as high as the fatality-rate from all causes in a standard scheme of treatment. In the case of the other schemes of intensive treatment the true fatality-rate cannot yet be assessed, but it is reputed to be lower than in the five-day scheme. The calculated mortality in the case of the twenty-day scheme is about 1 in 400.

Peripheral neuritis was a common and often severe complication in the neoarsphenamine series, and is encountered in cases treated with 'Mapharside' but in very much smaller numbers and seldom in severe form. Most of the toxic effects of the arsenicals which are seen in the course of a standard treatment can also be encountered in intensive treatment. Secondary fever and toxico-dermal reaction is a fairly common complication of the twenty-day scheme, and occurs about the ninth day.

Research by Padget has shown that 60 per cent of patients who had received so little as 4–6 injections of arsphenamine were 'cured', that is, they remained well and were serologically negative after a significant lapse of time. A 'cure'-rate of 85 per cent was attained only by those patients who had more than twenty-one arsphenamine injections combined with a heavy metal. The prognosis in the case of patients who received irregular or haphazard treatment was worse than in the untreated. The number of patients in civilian clinic practice in Britain who remain under treatment long enough to fall into this last group is regrettably small. Either patient or doctor may be

at fault, and the mechanism for the reclaiming of defaulters is not yet full enough in most areas.

It appears that intensive arsenotherapy offers in a short time as good, or even better, immediate results than the standard treatment scheme, but with a vastly increased risk of toxic effects and a risk of death four times as great. Between 95 and 98 per cent of patients complete treatment by intensive methods, and default is impossible in cases sent to hospital.

All the intensive treatment schemes so far detailed require the hospitalization of the patient. The risk of early muco-cutaneous relapse is about equal in the intensive and standard treatment schemes. Only early cases of syphilis can at present be treated by intensive methods, and the patients must be followed up for at least a year after treatment.

In the light of these limitations the application of intensive treatment must be restricted. An obvious use is in the case of key personnel in the Services, particularly the Navy and Merchant Marine. The benefits of returning a man to duty with no need for further treatment are obvious when it is remembered that many ships do not carry a doctor, and that haphazard treatment on standard lines may be worse than no treatment at all.

A potential use for intensive arsenotherapy might be in the case of persons who, notified under Regulation 33B, refuse to co-operate by placing themselves voluntarily under treatment when they are discovered to be infected with syphilis. This is naturally a hypothetical case and is open to criticism from both a legal and a medical point of view. Such persons, devoid of any sense of public duty, do however exist, and it would certainly be in the public interest to have them treated as rapidly as possible. In the United States such a policy is already in operation in at least one place.

A long-term policy in the public health aspects of syphilis must not be forgotten, for the sufferer from late effects such as general paralysis of the insane or cardiac disease may become a charge upon the State. We do not know what percentage of syphilitics treated by intensive methods may yet develop late phenomena. The aim in treatment is complete cure, and to accept any method which falls short of this, even if it offers immediate benefits in rapid and permanent surface sterilization in a high percentage of cases, may be to store up trouble for the future.

The aim in research into the treatment of syphilis is to discover a scheme which will occupy as short a time as possible, which will be free of dangerous toxic effects, give a high percentage of permanent 'cures', and can be used on out-patients. A clue has been given in the animal research work of Eagle and Hogan, who found that, within broad limits, the curative dose of 'Mapharside' with any one method of treatment was largely independent of the time period over which that treatment was given. Intravenous drip methods with 'Mapharside' were consistently less effective than repeated syringe injections over the same time periods. With regard to toxicity they found that on any schedule of injections the shorter the total treatment period the lower is the margin of safety. Assuming that these considerations apply in human syphilis, they have suggested a variety of possible schemes for trial. Patients are already being treated on the experimental lines suggested.

The treatment for early syphilis in the future may be a compromise between the present standard scheme and the intensive methods described above, and will probably last from four to ten weeks. The arsenical will almost certainly be an arsenoxide preparation injected by syringe at least three times a week, and bismuth will be used concurrently.

OBITUARY

Dr. F. L. Pyman, F.R.S.

THE news of the death of Dr. Frank Lee Pyman on January 1 at the early age of sixty-one, after a prolonged illness, will have been received with deep regret by his many friends. Pyman was an outstanding personality in the chemical world of twentieth-century Britain, and his experimental work in medicinal chemistry has been a not inconsiderable factor in fostering the respect in which British medicinal chemistry is held to-day.

Pyman entered Owens College, Manchester, in 1899, and, after graduating in 1902, went to the Polytechnic at Zurich, where he had the good fortune to come under the influence of Bamberger, who was then at the zenith of his fame. The dissertation which followed was published in 1904, and Pyman was granted his doctorate at the University of Basle. In 1905, on his return to Great Britain, he obtained a post with T. E. Thorpe at the Government Laboratory, but stayed only a few months as he felt he had little flair for analytical chemistry.

Circumstances in another branch of chemistry were, however, propitious. The late Sir Henry Wellcome had for a decade pursued an enlightened policy of establishing laboratories for scientific research, and had allowed the results of such research to be published, a policy which, it is true to say, had ushered a new era into British pharmaceutical chemistry. In furthering this policy, Wellcome had in 1905 appointed Jowett, who had carried out noteworthy investigations under Power's directorship of the Wellcome Chemical Research Laboratories, as head of the new Experimental Department of the Wellcome Chemical Works at Dartford. Within a year, however, Jowett was raised to the position of works manager, and the vacancy thus created was filled by Pyman. This was indeed a fortunate choice, since, over the ensuing period of eight years, a succession of model papers issued from this laboratory under Pyman's name which stand comparison with any chemical work published in Great Britain during the same period. The subjects covered ranged from local anæsthetics, mydriatics and hypnotics to arsonic acids, *iso*quinoline alkaloids, glyoxalines and the alkaloids of jaborandi and ipecacuanha; they probably reached the height of experimental perfection in the syntheses of histamine and histidine, and in the elegant results obtained in the study of the Hofmann degradation of tetrahydroberberine methosalts.

In 1914 Power persuaded Wellcome to allow him to return to the United States, and it was but natural that Pyman should succeed to the directorship of the Wellcome Chemical Research Laboratories at Snow Hill, a position he held until early in 1919. The war years were strenuously devoted to the production of drugs hitherto made abroad and, in particular, the difficult problem of the salvarsans claimed much of Pyman's attention. In addition, the ipecacuanha alkaloids, so important in the treatment of dysentery, were made to reveal more of their secrets.

The war years were unsettling years; Pyman had long cherished the ambition of a professorial chair, and in 1919 this goal was realized when he accepted the post of professor of technological chemistry in the Municipal College of Technology, Manchester. He entered on his new teaching duties with zest; he was an excellent lecturer, and for eight years he directed the researches of numerous students, the main theme being the chemistry of the glyoxalines. As glyoxalines are cyclic amidines, Pyman extended his investigations into this field, and the amidines were the subject of constant research up to the time of his death. The full fruits of amidine chemistry in its application to therapeutics—in this Pyman was a pioneer in Great Britain—have still to be reaped.

In 1927 Pyman was appointed director of research to Boots Pure Drug Co., Ltd., at Nottingham, a position he occupied until his death. Administrative duties were now paramount, and he regretfully left the test-tube and allowed it to be wielded by others under his stimulating direction. During this period a return was made to the chemistry of glyoxalines, the glycerophosphates, and the *iso*quinoline alkaloids, but new departures took Pyman into the field of organic salts of bismuth, long-chain amines and amidines, purgatives and derivatives of harmine and harmaline; studies of all of which were enriched by his long and ripe experience.

In 1935 Pyman was fittingly awarded the Hanbury Medal of the Pharmaceutical Society for original research in the natural history and chemistry of drugs. He was chosen as president of Section B (Chemistry) of the British Association at Nottingham in 1937, and his address was devoted to an account of the extensive researches of his colleagues, on amœbicides in particular, and on antiseptics.

To the outside world, Pyman's published researches are a lasting memorial to his memory. His friends, colleagues and pupils will, in addition, remember him as an English gentleman, staunch and straight and in whom there was no guile. Widespread sympathy will be felt for his widow, his three sons and two daughters in their tragic bereavement.

HAROLD KING.

NEWS and VIEWS

Institution of Electrical Engineers

Faraday Medallist

THE Council of the Institution of Electrical Engineers has made the twenty-second award of the Faraday Medal to Dr. Irving Langmuir, associate-director of the Research Laboratory of the General Electric Company in Schenectady, N.Y., for his outstanding contributions to electrical science. Dr. Langmuir's investigations have ranged over an extremely broad field. His work on hard vacuum valves, thyratrons and gas-filled incandescent lamps is widely known. He has also worked on atomic hydrogen welding and carried out fundamental researches on oil films; this latter work led to clearer understanding of such diverse topics as thermionics, heterogeneous catalysis and surface tension. Dr. Langmuir was elected a foreign member of the Royal Society in 1935 (see NATURE, July 6, 1935, p. 14), and three years before he had been awarded a Nobel Prize for Chemistry. The Faraday Medal is awarded by the Council of the Institution of Electrical Engineers not more frequently than once a year, either for notable scientific or industrial achievement in electrical engineering or for conspicuous service rendered to the advancement of electrical science, without restriction as regards nationality, country of residence, or membership of the Institution.

Honorary Member

THE Council of the Institution of Electrical Engineers has elected Sir Ernest Thomas Fisk to be an honorary member of the Institution. This distinction has been conferred upon him in appreciation of the services he has rendered in Australasia in the field of radio-communications. Sir Ernest, who is a past-president of the Institution of Radio Engineers (Australia), was managing director from 1917, and has been chairman from 1937, of Amalgamated Wireless (Australia), and also chairman of several other companies concerned with wireless. Originally a member of the Marconi Company, he joined a special mission to the Arctic in 1909. He has generally pioneered radio in Australia, including direct wireless communication with Great Britain, having received the first direct wireless message from England to Australia in 1918. In 1940 Sir Ernest was appointed secretary of the Economic Cabinet in Australia, and Director of Economic Co-ordination.

Agricultural Education in Great Britain

THE Minister of Agriculture has announced the Government's plans concerning the future of agricultural education. So varied have been the reactions to the recommendations contained in the Luxmore Report that it was natural that the Government should require time to digest the different points of view before reaching a decision. Two matters have been determined. The first concerns the future of the provincial and county advisory services, which are to be unified into one national service for the whole country directly under the Minister of Agriculture, and financed entirely by the Exchequer. This is virtually one of the Luxmore proposals, though it should be noted it is the system which has governed county advisory work during the War. War Agricultural Executive Committees have assumed the full responsibility for this work, and the majority of county council staffs have been seconded to these committees, while considerable additions to technical staffs have been made direct. The provincial advisory service has always been financed by the Exchequer, but the new proposals will remove this work from the control of the provincial colleges and university departments of agriculture. One cannot see any serious drawbacks to these proposals and

they will be endorsed by the majority of those engaged in this work at present.

The second proposal concerns the farm institutes. These are to be multiplied in number, but the provision of agricultural education at the farm institute level and below will remain a function of the local authority. In this sense the Government has wisely accepted the criticisms levelled against the Luxmore proposals. Discussions have proceeded as to the control which should operate in the case of the farm institutes, and as a piece of permanent machinery a joint advisory committee is to be set up by the Ministry of Agriculture and the Board of Education to advise on the general educational policy and methods of training at farm institutes, and in turn the institutes will be inspected by inspectors of the Board of Education and of the Ministry of Agriculture. It is a pleasing thought that the Government is now recognizing that steps must be taken at an early date to make available farm institute training, since it has been little short of a national catastrophe that the existing institutes were closed down at the beginning of the War and educational work at this level has practically ceased. The explanation is that staffs normally engaged in this work were diverted to the needs of food production; but since there has been a considerable influx of new blood into agricultural education work directly concerned with food production since the beginning of the War, it should now be possible to provide adequate staff for the re-opening of farm institutes at an early date. This will be in the best interests both of food production and the future of agriculture itself in Great Britain.

Social Security in the United States

In the discussions on social security in Great Britain, it has already been emphasized that, at least in part, social security is an international problem. Full employment, or the reasonably high level of employment pre-supposed in the Beveridge plan, depends on the general condition of world trade as well as on the social and economic policies pursued internally in Great Britain. For that reason alone the article on "Social Security Planning in the United States", contributed by Eveline M. Burns to *Agenda* of December 1943, is of general interest. It gives an appreciation of the general situation in the United States and of the lines of development and policy recommended in the Security, Work and Relief Policies Report of the National Resources Planning Board, the Wagner Bill proposing to set up a unified national system of social insurance, and the more recent report of the Planning Board on "Demobilization and Readjustment", which shows the complexity of the situation in the United States.

Any acceptable and realistic programme for the United States must take account of the great geographical diversity in living standards and real wage levels, and must be so devised as to operate within the limitations of a federal system of government in which the consciousness of State rights is very strong. Furthermore, many sections of the public still regard government action to assure the basic economic security of the individual with the gravest suspicion. Social security planning of the type envisaged by the National Resources Planning Board meets with strong opposition among those who believe that the job can be done by private enterprise. Moreover, there has been a surprising lack of public interest in the proposals of the report on demobilization and readjustment, with its emphasis on the vital importance of efforts to assure full employment and on the responsibility of the Federal Government to announce its vitally important policies as soon as possible for both economic and social reasons. The whole psychological attitude of Americans, and the present boom, tend to conceal the inadequacy of American social machinery for grappling with the problems of poverty and insecurity; and no great national ordeal comparable to the 'blitz' in Great Britain has strengthened the sense of communal responsibility and the desire to remedy some of the glaring social evils of the pre-war world.

Planetaria of the World

Mr. Roy K. Marshall has an article on the Planetarium in *Sky and Telescope* of November 1943, which announces the first public demonstrations in the Fels Planetarium of the Franklin Institute in Philadelphia. The remainder of the article is devoted to a historical survey of the planetaria which have been constructed at various times, starting with Archimedes, the story of whose machine for reproducing the motions of the planets is probably legendary. The first of such machines to be made, of the quality of which we can be certain, was constructed by Johannes van Ceulen de la Haye, in 1682, and it is still preserved in Leyden. The proper way to represent the heavens is to make a celestial globe so large that the observer can get inside it, and the most famous of these is the one constructed about 1758 by Roger Long, the first Lowndean professor of astronomy and geometry at Cambridge. It was about 18 ft. in diameter and thirty people could be accommodated on the platform inside it.

A list of known planetaria with dates and also the diameters of the domes is given. Of twenty-seven planetaria, twelve are installed in Germany, the largest, with a diameter of 98 ft., being at Düsseldorf, and the United States comes next in the list with a total of six. A short description of some of the instruments and also diagrams appear, and the subject will be continued in a later issue. It may be mentioned, though it is probably known to most readers already, that the name 'orrery', which is frequently applied to these instruments, is derived from the fourth Earl of Orrery (Charles Boyle), for whom John Rowley made an instrument. This was an improvement on the model made by George Graham for Prince Eugene shortly after 1700.

An Attack on Logical Positivism

The simple solution to philosophical problems, which those philosophers who describe themselves as logical positivists have propounded in the last ten years, are to-day coming under attack. In the issue of *Mind* of October 1943, Mr. John R. Reid, who, like many American philosophers, uses a rather elaborate and top-heavy nomenclature, in his article "Analytic Statements in Semiosis" strikes hard at the root of logical positivism by attacking its account of the distinction between analytic and synthetic statements. Briefly, according to the logical positivists, an analytical statement, for example, "Red is a colour", asserts no matter of fact, cannot be denied without self-contradiction, and needs no verification; whereas a synthetic statement, such as "What I see now is red", states matter of fact, can be denied without self-contradiction, and needs to be verified. An analytical statement needs no verifica-

tion because it says nothing about anything; it merely illustrates our verbal habit. In saying "Red is a colour", I am merely illustrating the verbal habit we have of grouping the class of things we call *red* under a larger class which we call *coloured*. If, however, I say "What I now see is *red*", this is no question of verbal habits, but a matter of fact, and what makes it true or false is just what I *am* seeing now.

Mr. Reid argues that this is not the whole story, pleading that verification is needed even in the case of the analytic statement. What he says, reduced to very simple terms, is this: "Verbal habits are not known to me by any mysterious form of cognition. The analytic statement 'Red is a colour' must be verified by the same *sort* of process as the synthetic statement 'What I now see is red'. I must check how people do in fact use words such as *red* and *colour*. I must check just what my own use is (because it *is* my own use does not prevent me being ignorant about it) and what I intend my use to be. Rules of English change, and as they change, it may be expected that analytic statements will change with them." In Mr. Reid's view, then, both analytic and synthetic statements require to be verified, the former by the intentions and verbal habits of people, the latter by facts and natural laws. The point is one which was worth making though it may not reduce the structure of logical positivism to ruins.

Problems of Colonization

UNDER the title "Ideas Sobre Los Fundamentos Bioclimaticos Y Biogeographicos Para Una Colonizacion Europea", in *De Gœa, Anales de la Sociedad Argentina de Estudios Geográficos* (7, 99–111), Walter Knoche sets forth a number of important points to be observed if colonization is to be a success. As a general principle, it is laid down that woods and forests should be protected, as they are valuable in preserving the climate, to say nothing of their aesthetic value and their use to future generations in preventing the spread of steppe and desert. Problems relating to the acclimatization of European colonies in different latitudes are considered, and also the difference in the aptitude for acclimatization of European immigrants from southern Europe or from the Mediterranean countries in comparison with those from north-west and central Europe. It is interesting to know that in torrid zones no colonists from north and central Europe are found who have any real expectations for their descendants, but this does not apply to certain southern European colonists. The difficulties of acclimatization in torrid zones are discussed and also the effects of certain climatic conditions, such as ultra-violet light which acts very differently in regions of high altitude, in temperate zones, and in tropical countries. Very short waves produce erythema while those that are longer are responsible for the formation of pigment which, while it reflects some heat, also absorbs some and, as a consequence, there ensues hypertension of the sweat glands. The southern European is better protected against the solar radiation in torrid regions than is the northern European, though the latter is now able to acquire an artificial pigment by means of sun bathing or special heat rays. The principle laid down by the Incas is recommended: "Colonize in the valleys similar to those existing in the previous State, and other parts of the earth with temperature and conditions like those from which we came; if cold, select cold; if hot, select hot".

Bell Laboratories Photographic Department

PHOTOGRAPHY is a necessary part of research and development work, and there has been a Photographic Department at the Bell Laboratories, 463 West Street, New York, ever since the building was erected for the Western Electric Company at the close of the last century. Beginning with a single photographer and camera, it grew with the organization it served until in 1941 it required the full time of nine men, and included developing and printing quarters and a studio with cameras and other facilities that permitted it to turn out some 4,500 negatives and 63,000 prints each year. By this time the facilities were old and needed replacement. A careful study was therefore made of all needs and the most efficient production methods, and an entirely new lay-out was made, new equipment acquired, and all needed facilities provided to do the work most efficiently. This new lay-out was just about completed when war came, bringing with it intensified work, longer hours and increased personnel, and there is no doubt that the greatly augmented demands for photographic services of various types would have greatly exceeded the capacities of the old facilities. With the new quarters and equipment, a staff of fifteen is now producing at the rate of 14,000 negatives and nearly 200,000 prints a year. The new quarters are described and illustrated in an article by E. Van Horn (*Bell Lab. Rec.*, 22, No. 2; October 1943).

Conductor Sagging on Overhead Lines

Messrs. C. O. Boyse and N. G. Simpson recently read a paper in London on this subject before the Institution of Electrical Engineers, in which the first part reviews overhead-conductor sags and tensions and their calculation on single spans and on complete lines, using parabolic formulæ throughout. A standard procedure and standard methods of calculation are recommended. The second part of the paper deals with the determination, with respect to the conditions prevailing in Great Britain, of the wind and ice loads to be applied to conductors for design purposes, and the stresses so produced in the conductors. The use of the term 'factor of safety' applied to overhead conductors is criticized, and suggestions are offered for revision of the Overhead Line Regulations of the Electricity Commissioners. The loads transmitted to the supports are also considered. Erection sags for low-voltage distribution lines are recommended for general adoption.

Sheet Steels for Electrical Plant

A PAPER entitled "A Survey of Electrical Sheet Steels for Power Plant and the Factors Affecting their Magnetic Properties" (*J. Inst. Elect. Eng.*, **90**, Pt. II, No. 17; October 1943) by Mr. F. Brailsford discusses magnetic sheet materials used for electrical plant, and represents an attempt to stimulate the interest of electrical engineers and others in this class of sheet steels, in which progress in relation to the commercial materials has been relatively slow. After a short discussion of the historical development, the limitations imposed upon designers of electrical plant by the existing materials are referred to. This is followed by a brief outline of the physical basis of magnetic processes and by a discussion of the factors which affect the magnetic properties of electrical sheets. Finally, reference is made to future possibilities. The problems involved in

the production of better electrical sheet steels concern not only the practical steel-maker and the electrical engineer but also, for their solution, the physicist, the chemist and the experimental metallurgist. There is a great demand in the electrical industry for better electrical steels, particularly for transformers.

Lepidopterous Larvæ in Stored Products

WAR conditions have made it essential to know the numerous kinds of caterpillars, as well as of other insects, affecting stored food in Great Britain. It was soon found that with few exceptions the available descriptions of these larvæ are quite inadequate for identification purposes. Being based mainly on colour it became necessary to use more precise methods. In a useful paper entitled "The Larvæ of the Lepidoptera associated with Stored Products" (*Bull. Entomol. Res.*, 163; Oct. 1943) by Dr. H. E. Hinton of the British Museum (Natural History), the chætotaxy and other structural features are relied upon for distinguishing the species. He deals with thirty-five species which include all the more important British kinds, together with seven which have not yet been recorded in Britain. In order properly to study the structure and chætotaxy of the larvæ it is necessary to preserve them in Pampel's fluid or alcohol or other preservative; dried specimens have, as a rule, too many of the critical setæ missing. Through the early researches of Dyar, Forbes and Fracker, and more recently of certain European workers, the classification of Lepidopterous larvæ has been placed on a relatively sound basis, although much still remains to be done.

Tuberculosis Survey in the Western Pacific

A GRANT of £28,600 has been made under the Colonial Development and Welfare Act to enable a tuberculosis survey to be made in Fiji. It is hoped to extend the survey to the British Solomon Islands Protectorate and the Gilbert and Ellice Islands Colony. The scheme will cover a preliminary survey only, mainly to determine the extent of the problem and the best means of dealing with it. A Government medical officer is undertaking preliminary work. A comprehensive scheme for the reorganization of the medical services of Fiji and the Western Pacific with assistance under the Act is contemplated, under which it is proposed to provide accommodation for four hundred cases throughout the area.

Road Research

A COMMITTEE of the Road Research Board of the Department of Scientific and Industrial Research has been appointed "to survey the field for research on the use of machinery in road construction and, if thought fit, to draw up a programme of research". The Committee is constituted as follows: Sir George Burt, Mr. R. M. Wynne Edwards, Mr. A. Floyd, Mr. W. Minty, Mr. W. P. Robinson, Dr. W. H. Glanville (director of road research), and Mr. G. Bird (secretary).

The Department has also arranged to resume and extend its researches on concrete roads as part of the programme of the Road Research Board. The new work, which will have as its general aim the improvement of the standard of construction in respect of durability of surface characteristics, will be undertaken in co-operation with the Cement and Concrete Association. The Ministry of War Transport is co-operating in both these schemes.

Earthquake in Turkey

YET another large earthquake has taken place in Anatolia. On the morning of February 1, a strong earthquake occurred to the north-west of Ankara. The epicentre was near the town of Gerede, which is 180 miles east of Istanbul and about 60 miles from the Black Sea. In Gerede itself about four fifths of the houses were destroyed, and here and in the province of Bolu (in which Gerede is situated) 310 people were killed. In the province of Changiri 517 were killed, mostly at Tcherkesh, while in Zonguldak Province 25 people lost their lives. The effects of the shock were widespread, and in the villages north-west of Ankara 103 deaths as a result of the earthquake are reported. Altogether at least 955 people were killed by the earthquake and its effects, and some thousand others were injured. Faulting occurred along the motor-road from Ankara through Gerede and Bolu to Ismid, and communications were cut between Istanbul and the Kandili Observatory on the eastern shore of the Bosphorus. Snowstorms have hampered relief work. Strong tremors were felt at Adabazar, Ismid, Haidar Pasha, Smyrna, Kaisarieh and Brusa. The shock was registered at Kew Observatory in England at 4.28 a.m., the maximum ground movement at 4·41 a.m. being greater than one millimetre. This is the fourth great earthquake, besides numerous others of smaller intensity, which has occurred since what was probably the greatest Turkish earthquake—that of Erzinjan in December 1939.

Announcements

SIR HAROLD SPENCER JONES, Astronomer Royal, has been elected an honorary member of the American Astronomical Society.

DR. WILLIAM CULLEN, the distinguished consulting chemical and metallurgical engineer, has been elected president of the Science Masters' Association in succession to Prof. Frederick Soddy.

PROF. E. K. RIDEAL, professor of colloid science in the University of Cambridge, will succeed Mr. Wallace P. Cohoe, a well-known American consulting chemist, as president of the Society of Chemical Industry, at the annual meeting of the Society to be held in July.

PROF. P. M. S. BLACKETT, Langworthy professor of physics at the University of Manchester, has been elected president of the Association of Scientific Workers as from February 1. During the War, Prof. Blackett is working for the Admiralty; he is widely known for his work on nuclear physics and cosmic rays.

THE Council of the Institution of Electrical Engineers having sanctioned the formation of a Wireless Group for Cambridge and District, a provisional committee has been approved, under the chairmanship of Mr. C. R. Stoner, with Mr. D. I. Lawson as secretary. The inaugural meeting will be held in the Engineering Laboratories of the University on February 17.

THE A. Cressy Morrison Prize Committee for 1943 of the New York Academy of Sciences has awarded prizes of two hundred dollars each to W. A. Ritchie, Rochester Museum of Arts and Sciences, Rochester, N.Y., for a paper on "The Pre-Iroquoian Occupations of New York State", and to A. Grobman, University of Rochester, Rochester, N.Y., for a paper on "The Distribution of the Salamanders of the Genus Plethodon in Eastern United States and Canada".

Terminology of Nucleic Acids

So far as is known at present, nucleic acids are of two types, differentiation depending on the nature of the sugar which is present. In one type, the sugar is a pentose, and in those examples which have been sufficiently investigated, this pentose is *d*-ribose; the nitrogenous radicals are those of guanine, adenine, cytosine and uracil. In the other type, the sugar is a desoxypentose, and in those cases where examination has been adequate, this sugar is *d*-ribodesose, and the nitrogenous radicals are those of guanine, adenine, cytosine and thymine (5-methyl uracil). A convenient source of an acid of the former type is yeast, and the acid from that source became known as 'yeast nucleic acid'. Pentose nucleic acids were also thought to be peculiar to plants, and as a result the term 'plant nucleic acid' came into use, with an implication that all pentose nucleic acids from whatever source are identical; consequently the terms 'yeast nucleic acid' and 'plant nucleic acid' became synonymous. A satisfactory source of an acid of the second type is the thymus gland of animals, so that the acid from that source became known as 'thymonucleic acid'; and since it was believed that acids of this type were characteristic of animal tissues only, the term 'animal nucleic acid' came into vogue, with the implication that all nucleic acids of the desoxypentose type are identical. Thus the terms 'thymonucleic acid' and 'animal nucleic acid' became synonymous.

With the progress of knowledge it became clear that these generalizations were inaccurate, and it was suggested[1] that it is necessary to define a nucleic acid by referring both to its origin and its type. In this way alone, in the light of present information, is it possible to avoid future confusion, until such time as it can be stated with certainty either that two (or more) individual nucleic acids exist and that all examples of each are identical in chemical constitution, or that two (or more) types of nucleic acid exist and that each type comprises a number of examples of related but different constitutions.

Recently, however, Pollister and Mirsky[2] suggested that the names 'chromonucleic acid' and 'plasmonucleic acid' should be used by biologists to denote the nucleic acids called by chemists 'desoxyribose nucleic acid' and 'ribose nucleic acid' respectively. It seems to us that this suggestion has little to recommend it, and is, in fact, retrograde.

The adoption of these terms would be open to the objections based on constitutional reasons mentioned below, and their application to denote the two types of nucleic acid, pentose and desoxypentose, would not clarify the present situation, and would merely replace names based on chemical structure or biological source by other terms not wholly accurate because based on an incorrect statement of biological distribution. Thus, Pollister and Mirsky state that "it is now clear that desoxyribose nucleic acid is normally restricted to the chromatin of the cell nucleus", and that it is "now certain that the ribose nucleic acid, by contrast, is found either in the cell cytoplasm or in the plasmosome (nucleolus) of the cell nucleus". This statement is barely tenable at the present time without special emphasis of the word 'normally', since it is known, for example, that the viruses of psittacosis and vaccinia[3] contain desoxypentose nucleic acid and that the magnesium salt of ribonucleic acid forms part of the surface structure of Gram-positive organisms[4]. Who can predict what the future may bring in the way of other exceptions to Pollister and Mirsky's basis of definition?

Further, Pollister and Mirsky's proposed classification is founded on the recognition of certain chemical units detected only after the disintegration of complex molecules which occur in a considerable variety of biological sources. It ignores entirely in what ways those units may be joined together. There is at present no evidence to show whether the nucleotide components are united in the same mode and pattern in the different examples of each of the two types of nucleic acids, that is, that such examples have, in fact, identical chemical constitutions. The adoption by biologists of Pollister and Mirsky's proposed classification would obscure potential differences, which if they exist cannot fail to be significant.

It seems necessary, therefore, to reiterate the suggestion made more than five years ago that, until the position becomes clearer, a nucleic acid should be defined by reference to its origin and type (pentose or desoxypentose); closer specification of the type, for example, *d*-ribose or *d*-ribodesose, is to be welcomed when justified on sound chemical grounds.

Vitamin A Aldehyde

WITH reference to Dr. Morton's suggestion regarding the role of vitamin A aldehyde (axerophthal) in the chemical changes involved in photo-reception[1], it may be of interest to mention that we prepared this substance some eighteen months ago by Oppenauer oxidation of vitamin A alcohol with aluminium *iso*propoxide in the presence of acetaldehyde. The ultra-violet absorption spectrum of the aldehyde showed maxima at 350 and 368 mμ in *cyclo*hexane and a band at 657 mμ in the antimony trichloride reaction, and was characterized by the formation of a 2:4-dinitrophenylhydrazone, m.p. 207–209°. On Pondorff reduction, it regenerated vitamin A alcohol (abs. max. at 330 mμ in the ultra-violet and at 620 mμ in the antimony trichloride reaction) which was characterized by conversion into 'cyclized' vitamin A (abs. bands at 390, 370 and 350 mμ in the ultra-violet and at 620 mμ in the antimony trichloride reaction). On condensation with acetone in the presence of sodium ethoxide, the aldehyde furnished axerophthylideneacetone[2].

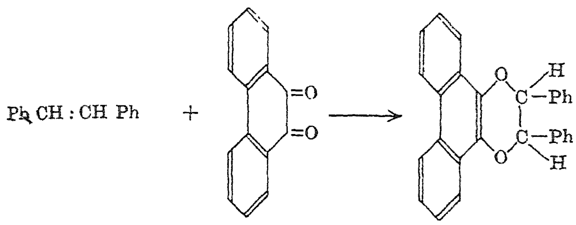
Reactions of Ethylenes with 1,2-Diketones in Sunlight

WE have found that ethylenes, for example, styrene, stilbene and triphenyl ethylene, react with 1,2-diketones when dissolved in benzene (thiophene-free) and exposed to sunlight. The experiments were carried out in 'Monax' glass tubes in an atmosphere of carbon dioxide. The reaction between phenanthraquinone and stilbene, which proceeds very rapidly, may be illustrated by the following scheme :



The nature of the product (m.p. about 260° with decomposition) is established by the fact that the photo-product is colourless (therefore no longer having the quinoid structure of phenanthraquinone) and when heated above the melting point, it decomposes into phenanthraquinone and stilbene. The action of concentrated sulphuric acid on it yields phenanthraquinone.

A full report describing the wide scope of the reactions mentioned in the title will be published soon.

Topography of a Quartz Crystal Face

IN a recent communication[1] a brief description was given of a multiple-beam interference method which can reveal submicroscopic detail upon the surfaces of crystals, and some preliminary data for cleavage faces of mica and selenite were recorded. This method has now been applied to reveal the topographical

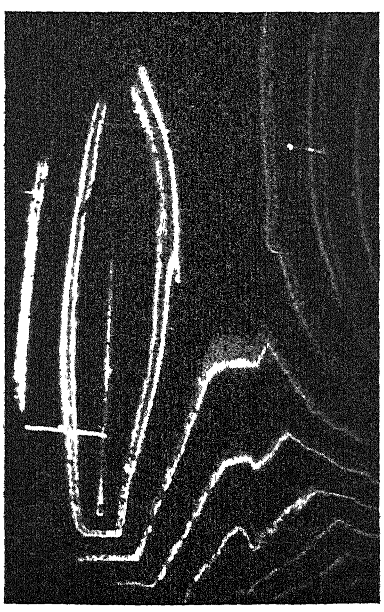

FIG. 1. Transmission fringes.

FIG. 2 Reflexion fringes

features of a highly lustrous (100) face of a left-handed quartz crystal. Typical interference contours for this face are shown in Figs. 1 and 2. The particular pattern recorded in any exposure is determined by the angle of inclination between the interference surfaces, and the contour patterns, although superficially different, give the same interpretation of surface structure when this is taken into account.

Fig. 1 shows *transmission* fringes over the larger part of the (100) face, the optical conditions being such as to prevent the whole of the face being covered. Both green and yellow mercury fringes appear. Fig. 2 shows *reflexion* fringes of the same face (green only), with a different inclination between the interference surfaces. The fringes are remarkably sharp, particularly those in reflexion, and the precision is so high that faces with angles of no more than 1/50 of a minute of arc between their normals can be measured. This is true even for quite small facets, and, of course, far exceeds the Rayleigh diffraction limit of the goniometer.

The interference contours reveal considerable detail, and each kink and bend in the fringes has true topographical significance and can be interpreted accordingly. The patterns show the existence of a small number of large vicinal faces covering the entire (100) face. These are inclined to each other at very small angles varying from 0·50′ to 9·00′. Furthermore, the surfaces of these vicinal faces are in most cases slightly curved, with radii of curvature varying from 60 to 20 metres. In some cases the ridge formed by the junction of two vicinal faces has not a constant angle but exhibits considerable, but continuous, variation along the ridge length.

The visual markings characteristic of a (100) face in quartz, namely, fine striations, inverted V markings and small triangular patterns, each show their own influence upon the interference pattern, and their topographical features have been determined. The striations have been found to be either minute ridges or ruts, the height (depth) being only 100 A. (that is, 20 molecules). Both ridges and ruts have been observed. The inverted *V* markings reveal small discontinuities in level in their immediate neighbourhood, of the order of small fractions of a wave. The triangular markings are found to be small submicroscopic projections, which are tetrahedra, some 450 A. in height (that is, 90 molecules), and with vicinal face angles of the order of 2′ or 3′.

The perfection of the reflected system of fringes shows that the experimental procedure employed can be applied widely to include all types of crystals with moderately large approximately plane surfaces. Translucent, opaque, and in fact metallic crystals or even crystal aggregates, as well as transparent crystals, can be studied, and it is clear that the procedure opens up considerable possibilities. The optical adjustment in reflexion is no more difficult than in transmission, and the photographic speed is increased by a factor of about 30. Fig. 1 required a 1-minute exposure, Fig. 2 required 2 seconds. (The magnifications of the figures are not quite identical.)

Complete details concerning the experimental arrangements, which are critical, together with the complete topographical analysis of the crystal face, have been communicated elsewhere.

It may indeed be considered that this procedure functions in a region intermediate between that available to study by X-rays and by the microscope respectively.

Ascorbic Acid and Hip Fertility in Rosa Species

PREPARATIONS rich in vitamin C made from the flesh of ripe Rosa receptacles are now being produced on an industrial scale, in Sweden as well as in other countries. The systematic examination of native and cultivated species of Rosa has shown that considerable differences occur in their content of ascorbic acid. One of the present authors (J. S.) published in 1941 a paper on the results obtained at Kärnbolaget AB, Stockholm, up to that year. In that publication the chemical methods used were described in considerable detail, as was also the relation of ascorbic acid to yearly fluctuations, chromosome number and taxonomical position. Previously, Gustafsson[1,2] and Gustafsson and Håkansson[3] were engaged in genetical and cytological experiments on *canina* roses and undertook in 1942, with the financial support of Kärnbolaget AB, a population analysis of ascorbic acid in the roses of south Sweden. By this joint work a relation was discovered that seems to be of general importance, namely, the influence of hip fertility on the amount of ascorbic acid.

Successful cross-experiments were carried out in 1932 and 1934 between various *R. canina*, *rubiginosa* and *rugosa* biotypes. Especially the hybrid series *R. canina* II × *rubiginosa* and its reciprocal have proved interesting in several respects and have been carefully studied with regard to ascorbic acid content. With *R. canina* as mother the hybrids form large hips, rich in ascorbic acid ; but at the same time containing very few fruit, that is, they are largely infertile. Most of the reciprocal hybrids, with *R. rubiginosa* as mother, give late-ripening, bottle-shaped hips, having a low content of ascorbic acid, but being normally fertile with a high number of nuts per hip. These reciprocal differences made us assume that the infertility is responsible for the high content of ascorbic acid, or, in other words, that the fewer nuts per hip, the more ascorbic acid, within similar hybrid series and in related species. The proof this assumption was afforded by a monosomic plant in the *R. rubiginosa* × *canina* II series (Pl. 34), this having a low fertility owing to the loss of one chromosome (34 instead of 35), but simultaneously a highly increased vitamin C content. The results are given in Table 1.

TABLE 1

	Ascorbic acid as per cent dry matter of the flesh		Nut content as per cent of the hip weight	
	1941	1943	1941	1943

(The analyses of *R. canina* I × *rugosa* and *R. canina* II × *rugosa* run in the same direction, but so far the content of ascorbic acid in the *R. rugosa* parent has not been sufficiently determined to allow definite conclusions.)

This negative correlation of hip fertility and content of ascorbic acid was also demonstrated in three other sets of material.

In 1942 the ascorbic acid and the nut content were determined in 155 different spontaneous *R. canina* individuals, the hips of which were collected by Gustafsson and then immediately examined. Most of the shrubs belonged to the *R. eucanina* and *afzeliana* complexes (Case 1).

Similarly, a series of samples were taken by Schröderheim[4] from 41 different parcels delivered for industrial production in 1943 from various parts of south and middle Sweden (Case 2).

In these two cases the material was biologically heterogeneous. In order to examine the corresponding conditions in one and the same species, samples of 164 *R. rugosa* individuals grown at Närlunda, not far from Stockholm, were analysed. Owing to the heterozygosity of this species in Nature most of the individual shrubs probably represent different biotypes, but every one falls within the boundaries of the species (Case 3).

The *P*-values were determined by analysis of the co-variance[5,6]. The data obtained are given in Table 2. The regression is expressed in such a way that the coefficient, −0·037, to exemplify from Case 1, implies an *increase* by 0·037 per cent in ascorbic acid content for every 1 per cent *decrease* in fruit content.

TABLE 2.

	Average fruit content in per cent of hip weight	Average ascorbic acid in per cent dry matter of hip flesh	Corr. coeff.	Regr. coeff	*P*
Case 1	34·76	2·82	−0·21	−0·037	0 01–0·001
Case 2	31·63	2·50	−0·75	−0·120	<0 001
Case 3	20·82	3·50	−0·17	−0·032	0·02

Consequently, the fertility of the hips shows an obvious and significant influence on the amount of ascorbic acid. This fact in its turn may signify that the ascorbic acid (or some sort of precursor or derivative) takes direct part in the seed and nut development, so that it is stored up in the receptacles and not consumed if for some cause (genotypically or environmentally conditioned) the nuts are few in number and the ascorbic acid is not needed in metabolism.

These results point to a reconsideration of the connexion between chromosome number and vitamin C content in apples, tomatoes and other fruits[7,8]. Especially in apples, where the fruit is false and constructed in a similar way to the rose receptacle, we may conceive that the higher vitamin C content of triploids as compared with that of the diploids is due to the infertility itself, as well as to the chromosome number and the genotype.

Finally, it ought to be stressed that for the full ripening of a Rosa receptacle only one or two fruits are required. In fact, the above-mentioned *R. canina* ♀ × *rubiginosa* ♂ hybrids flower and fruit abundantly, although the number of fruits per hip is very low.

Manganese Deficiency in Oats

E. S. TWYMAN[1] stresses the value of the water-culture technique used by Stout and Arnon[2] in investigations into the effects of traces of the heavy metals on plant growth. The demonstration of the rapidity with which grey-speck lesions can be produced in oat seedlings is, however, not new, and directs attention to the need to consider carefully the chemical background to all water-culture investigations. More than fifteen years ago it was shown[3,4] that, provided proper precautions were taken to exclude manganese from the culture solutions, grey-speck lesions invariably developed in oat plants in four weeks or less. Recent work by Arnon and Stout[5] on the effect of molybdenum on the growth of tomatoes has been confirmed by me[6] in regard to oats, so that the response obtained by Twyman to the group of seven elements (aluminium, molybdenum, titanium, vanadium, tungsten, nickel and cobalt) cannot be separated from the response known to be due to one of them.

In all critical water-culture investigations, it is necessary to consider carefully the chemistry of the elements under investigation, so as to appreciate the possible sources of contamination by them, the effective means for their removal, and specific tests to demonstrate their absence. Thus, in the case of investigations into manganese deficiency, it can be shown that water from a well-designed tinned-copper still and block tin condenser is entirely satisfactory, although such water would not be in the least suitable for investigations into the effects of copper and certain other heavy metals on plant-growth. For this, water redistilled from all-glass apparatus is essential. Water from a tinned-copper still has been found to contain 20–80 μgm. of copper per litre, depending on the condition of the tin coating of the still. In many cases high-grade analytical reagents can be shown to be free from manganese while other reagents, such as magnesium sulphate and iron salts, almost invariably require specially devised methods for their purification from the last traces of manganese. Fortunately, many of the methods for the removal of this element will, when properly carried out, also eliminate the last traces of copper, zinc and certain other heavy metals. Not all these methods will be equally effective for the removal of molybdenum, which exists as the molybdate ion in alkaline solutions, or for non-metallic elements such as boron. Incidentally, the diphenylthiocarbazone test does not detect either of these elements, and it is not correct to assume that methods suitable for the elimination of a particular element, or group of elements, will also ensure general purification of the reagents from all other important trace elements.

Traces of manganese and zinc are readily obtained by plants from many types of glass ordinarily used for culture vessels. In critical experiments involving these elements, it is therefore necessary to protect the surface with paraffin wax, or preferably to use vessels of 'Pyrex' glass. Many of the better quality resistant glasses do not yield significant traces of copper to plants growing in vessels made from them, hence they are quite suitable for such investigations.

In many experiments the amounts of the trace elements contained in the seed must not be overlooked for, after satisfactory control of all reagents and water has been obtained, these amounts become of prime importance. It is often necessary to select seed as low as possible in the element under investigation. The natural variation may be very considerable; I have noted a range of 10–75 mgm. of manganese per kgm. of dry matter and 0·9–11·3 mgm. of copper per kgm. for Algerian oats. Other investigators have also found considerable variation in seeds generally. Experiments recently carried out by me indicate that the relatively greater amounts of copper contained in rye grain account for the greater growth made by this plant when oats and rye are grown under identical conditions in nutrient solutions, either in the absence of copper or in the presence of amounts of the order of 1–2 μgm. per litre.

If adequate means of chemical control had been available to, or attempted by, the early investigators of the trace elements, to ensure the purity of the water and reagents used and the suitability of the glass of the culture vessels, it is reasonable to assume that the essential nature of manganese, boron, copper, zinc, and molybdenum would have been demonstrated many years sooner.

[6] Piper, *J. Aust. Inst. Agric. Sci.*, **6**, 162 (1940).

MR. PIPER has rather missed the point of my communication, which was to direct attention to the value of the Arnon technique, since this, so far as I was aware, had not until then been used in Great Britain. I exemplified this value by quoting some of my own experiments with oats. I certainly did not wish to suggest that there was anything new in producing the symptoms of grey-speck disease in water culture, and I had assumed that all those interested would be well acquainted with the work of Samuel and Piper, published some fifteen years ago, since it was this work which established the proof of the connexion between grey-speck disease and manganese deficiency.

With regard to the effect of molybdenum on the growth of oats, I would say that I have now been able to read Mr. Piper's paper which, probably owing to war conditions, had not reached me at the time of the publication of my earlier letter. There is now no doubt that molybdenum is an essential element for the growth of oats. It still remains to be proved, however, whether one or more of the other elements of Arnon's original *B*7 group (chromium, titanium, vanadium, tungsten, nickel and cobalt) were also responsible for at least part of the response obtained in the experiment reported in my communication.

I would like to take this opportunity of correcting an error made in my letter where I included aluminium among the seven elements of the *B*7 group; this should have been chromium. Thus for aluminium read chromium in Mr. Piper's letter in this issue.

Development of Botanical Investigations at Rothamsted

IN an article in NATURE of July 24 entitled "Development of Botanical Investigations at Rothamsted", the following statement is made with reference to 'minor' elements and plant growth[1]:

"Stimulation with minute traces of elements was far more difficult to demonstrate, though some indication was obtained. Following up an accidental clue obtained in 1921, Dr. K. Warington proved conclusively that in the absence of a trace of boron, growth of broad beans was completely checked. . . ."

I am not sure what constitutes an "accidental clue" in scientific investigations, but as a matter of historical interest in the progress of our knowledge about the effects produced by minute quantities of boron on the growth of broad beans, attention might be directed to the following statement made by Dr. Warington in the introduction to her classical paper published in 1923[2].

"In some experiments carried out by Dr. J. Davidson at Rothamsted in 1920 in connection with the bean aphis, broad bean plants in water culture solution supplied with a small quantity of boric acid were strikingly superior to the rest of the series; accordingly, the present investigation was undertaken in order to determine more fully the action of boric acid on the broad bean and certain other plants."

The experiments referred to formed part of a wide programme of research, which aimed at finding out by means of controlled experiments with the black aphis on broad beans "whether changes can be introduced in the sap of the growing plant, so as to affect its suitability as food for the aphids, and at the same time not adversely affect the plant"[3].

The British Elm Flora

THE view expressed by Howard in his interesting article on the elm tree[1], that there are but two species represented in the United Kingdom "with perhaps nine or more hybrids or varieties", is no longer accepted by botanists. It is true that the common or English elm and the wych elm are the most widely-spread species and both are undoubtedly native. The wych elm, the correct name for which is *Ulmus glabra* Huds., occurs throughout the country, but the common elm is concentrated in the south, thins out in northern England and is probably only planted in Scotland. This species is now known as *U. procera* Salisbury, the Linnean name *U. campestris* being a *nomen ambiguum*[2]. Its distribution in the country is quite natural, and so far it has been recorded from the Continent only as a planted tree; the evidence strongly favours the view that it is endemic, in spite of the misgivings of earlier writers.

The parts of England to the south and east of a line drawn from the Bristol Channel to the Humber has an unusually rich elm flora, including several species that appear to be endemic, though their status cannot be finally settled until a critical examination has been made of the elms of the neighbouring parts of the Continent. The Cornish elm, *U. stricta* Lindley, is abundant in Cornwall and Devon, thins out eastward into Dorset and is represented by a variety, the Goodyear elm, var. *Goodyeri* Melville[3], to the south of the New Forest, and by a further variety, the Wheatley or Jersey elm, var. *sarniensis* (Loud.) Moss, in the Channel Islands and possibly adjacent parts of France. The three varieties form a geographical series or topocline increasing in breadth of leaf from west to east[4]. In low-lying parts of the river valleys, from the Wash across to the Severn, is found the most distinctive and elegant of our endemic species, the Plot elm, *U. Plotii* Druce[5]. The Continental smooth-leaved elm, *U. carpinifolia* Gleditsch (*U. nitens* Moench), is doubtfully native, but we have instead the East Anglian elm, *U. diversifolia* Melville[6], having shoots with symmetrical leaves interspersed with others bearing the usual lop-sided leaves and another species with intergrading varieties extending across the Midlands and East Anglia. The latter awaits description, as does the small-leaved elm of East Anglia related to the Plot elm.

The Dutch elm, × *U. hollandica* Mill. var. *major* (Sm.) Rehd. and the Huntingdon elm, × *U. hollandica* var. *vegeta* (Loud.) Rehd., are widely planted; both are presumed to be hybrids of the wych elm with *U. carpinifolia* Gleditsch. There are numerous natural hybrids; the wych elm apparently hybridizes freely with all the other species except *U. procera*, which normally has finished flowering before the wych elm starts. It is probable that many of the hybrids are fertile, as intergrading series of hybrid forms connect the species. The intergrades are particularly numerous between *U. glabra* and *U. Plotii* and may be arranged in sequences on leaf shape

characters[7]. Horwood's Midland elm, *U. elegantissima*, is a hybrid of this group.

There is a wide field for investigation in the physical properties and economic value of our native elms. Much of the ill-repute with which elm timber is regarded may be due to admixture of unsuitable hybrids. Without botanical assistance both forester and timber merchant may accept inferior hybrids as wych elm, since the habit of this species appears to be a dominant character. Field observations suggest that interaction or recombination of genes occurs in the hybrids, and may result in wood so brittle that branches half an inch in diameter break under slight pressure with a short fracture. On the other hand, it is probable that improved strains for timber production could be selected and this might be coupled with resistance to the Dutch elm disease, *Ceratostomella ulmi*. Of our native species, the wych elm is the most susceptible, but some of its hybrids are even less resistant, notably the Dutch elm and many of the heterogeneous forms hitherto imported as seedlings from the Continent. The Cornish elm, the English elm and the Plot elm all appear to be comparatively resistant.

R. MELVILLE.

Royal Botanic Gardens,
Kew.

[1] Howard, A. L., NATURE, **152**, 636 (1943).
[2] Melville, R., *J. Bot.*, **76**, 261 (1938).
[3] Melville, R., *J. Bot.*, **76**, 185 (1938).

[5] Melville, R., *J. Bot.*, **78**, 181 (1940).
[6] Melville, R., *J. Bot.*, **77**, 138 (1939)

SURELY Dr. Melville is misquoting me. My statement was: "There are about twenty species, of which only two are prominent in the United Kingdom —the common elm (*Ulmus campestris*) and the wych elm (*Ulmus montana*)—with perhaps nine or more hybrids or varieties".

The article contributed by Dr. Melville, who has made a comprehensive study of the elm tree and has published many interesting articles in the *Journal of Botany* and that of the Linnean Society, recalls to my mind a conversation which took place about forty-two years ago between Henry John Elwes and Sir Hugh Beevor, one of whom at the time was president of the Royal English Arboricultural Society. The subject was whether the elm was indigenous to Great Britain, and covered much the same ground as that traversed by Melville. It seems difficult to understand that those keen-eyed, closely observant men who came before and followed Evelyn would be likely to have been mistaken. The intelligent woodman clearly recognizes the difference between the common elm, the wych elm and the Dutch, the last-named of which assumes a quite different appearance in its habits from either of the others.

There is no doubt that the elm, with the exception of those sorts already mentioned, and possibly the Cornish elm, varies greatly, probably more than any other of our trees.

The regular planting and rearing of English elm has received little attention during the last two hundred years, and the greater majority of those trees that have established themselves have been self-sown. During this period a great many aliens have been introduced into Great Britain—American, Canadian, European, Japanese, etc. Is it possible that this has resulted in the development of hybrids ?

ALEXANDER L. HOWARD.

Euston Road, N.W.1.

An Undescribed Feature in the Drill (*Mandrillus leucophaeus*)

GLANDULAR modifications of the skin over the sternal region in primates have been described in the orang (Schultz) and in the Gelada. Something of the kind evidently exists in the drill (*Mandrillus leucophæus*) and possibly also, therefore, in the mandrill (*M. sphinx*), though full details cannot be given pending histological study of the part. No reference is made to such a structure by Sonntag.

My notice was first directed to the possibility of a sternal cutaneous modification in a male drill which has been in captivity under my observation for seven years. After passing the pubertal epoch at the approximate age of five years, he developed, upon the middle of his chest, between the nipples, a tuft-like patch of specialized hairs. These are longer, coarser, stiffer and of duskier colour than the general ventral covering of short, soft, whitish hairs. They project caudalwards and at times are slightly more upstanding than the hairs of the neighbouring areas.

This hairy tuft is the basis of a very curious and extremely amusing behavioural pattern which is observed *only* when the animal is presented with pieces of fresh twig or bark derived from a mango tree (*Mangifera indica*). After smelling the twig, he rubs it in a vertical direction on his mouth and chin (maximum pressure being on the chin) and swiftly passes it thence to the sternal tuft, thrusting the chest forwards to meet it. This procedure is repeated many times in rapid succession. Each time a return is made from sternum to lips, profuse salivation takes place, until his beard is literally dribbling with saliva, much of which is transferred to the sternal tuft in the frenzied antics accompanying the act. The animal apparently realizes that this behaviour has an entertainment value, and this stimulates him to adopt the most inconceivable bodily postures in an endeavour to obtain the maximum number of contacts between the twig and his chest in the minimum time. The animal is quite rational in his other behaviour, so that I do not consider this to be merely a personal idiosyncrasy.

No adequate explanation can at present be offered for this behaviour; but it is clearly initiated by the characteristic odour of the mango bark (the fruit has no similar effect). Some pleasurable sensation is evidently experienced either (*a*) from contact between the moistened bark and the sternal tuft, or (*b*) the twig serves to transfer a possible cutaneous secretion from a gland on the chest to the lips and nose, whereby pleasure is evoked by the taste or smell thereof, or (*c*) both.

There is no direct evidence of any sexual significance in the specialization here referred to, except that so far it has only been observed in an adult male. I have examined cadavers of two female drills (one juvenile and one sub-adult) and found no modification of the hair, and at any rate no macroscopic indication of a cutaneous gland in the intermammary area. The matter is being further investigated.

REGIONAL PLANNING AND RESEARCH IN THE UNITED STATES

IN the field of industrial research, the United States of America have always and with very good reason been held up as an impressive example; and a remarkable illustration of this truth now comes in a recent report on New England*. It is the more timely and interesting since it deals also with regional planning and location of industry in close relation to research.

New England comprises the six comparatively small States of Maine, Vermont, New Hampshire, Massachusetts, Connecticut and Rhode Island; accounting for only 2 per cent of the total land areas of the United States, but contributing 8·6 per cent to the country's manufacturing industry, and employing 12·1 per cent of the wage earners. There is no need at this time to describe in any detail the manifold industries and the spirit of enterprise and courageous and intelligent self-help which distinguishes its people: the point of main interest is the energy and vision with which New England is dealing with present and prospective problems of industry and social life, and its very faithful application of research methods to regional development.

Regional planning in this section of the United States may be said to date back to 1925, when the New England Council was established to co-ordinate economic interests and act in a broad sense as a research agency, both in the technical and the social aspect. It is democratically based on individual and corporate representation, and its one aim is to advance the economic and cultural welfare of the six States. One of its first actions was to set up a research committee, when Lincoln Filene—a great name in American industrial history—was appointed chairman. It initiated complete surveys of industry and technical research facilities, investigated cultural and recreational development, agricultural well-being, community growth, and in a word the whole field of communal and industrial activity.

In 1938 the president of the Council approached the Massachusetts Institute of Technology and asked the Institute to assist in the setting up of a New Products Committee. This assistance was readily forthcoming, and four sub-committees were soon afterwards established. (1) "Research Day" in New England, which aimed at setting apart one day at least in the year when all New Englanders should think about research and its vital importance to their welfare; become, in fact, research-minded. Meetings would be held, papers read, and speakers invited to tell the people in plain language some of the latest achievements of science. Special efforts would be made to interest the smaller firms, and discover means whereby they too should benefit from technological advance. (2) Natural Resources, to undertake complete surveys. (3) New Manufactures, mainly to study the various materials and products imported into New England, with the view of determining which of these could well be produced within the regional borders. Purchasing agents' associations were called in to help, and many new lines of industry were thus indicated, including fibre glass textiles and the like. At first sight it would seem that New England might benefit at the expense of other parts of the United States if this policy should be largely followed; but this is not necessarily the case, for manufacturers of these products in other parts would be invited and encouraged to establish branches in New England.

(4) Venture Capital. This sub-committee is of particular interest. As the name implies, its function is to finance the new ventures, and by skilful publicity, based on the many real advantages offered by New England to investors, to attract capital from outside and encourage those within the region to put their money into local industries rather than into safe gilt-edged securities. Hitherto brains and capital are said to have been the principal exports, but now it is earnestly sought to retain both at home for investment there. If other regional units of the United States follow the New England example, then there would be keen rivalry among them in attracting industrial enterprise, including capital, labour, research workers and management. Assuming that such competition is desirable if properly controlled and guided in the national interest, then it constitutes the real kernel in the location of industry problem.

Several interesting questions arise here of vital national and international importance as to the right kind of competition and its judicious balance with co-operation. It is obviously undesirable that one region within a country should gain at the expense of others, just as it is for one country to gain at the expense of others. These difficulties cannot be discussed fully here, but so far as New England is concerned, it is held that the most important part of the work of the Council is survey and research in order to ascertain quite definitely what are the determining factors involved in the question: Where shall we locate our business? In New England, in the Middle West, in some other part of the United States, or abroad? The last-named possibility should not be overlooked by taxation authorities, by labour leaders and others. It was indeed suggested early in the history of the Council that a permanent organization should be established to study industrial opportunities which offer the chance of major development, and assemble full and complete factual information on which industrial leaders could base a sound and intelligent judgment. Small firms would be welcomed equally with large.

Accordingly a Research Foundation was set up in 1941—the New England Industrial Research Foundation Incorp.—with a small operating staff and trustees of management. The seventeen founders were carefully selected to represent the most varied interests throughout the six States. Funds were readily forthcoming, and these, together with the fees payable to the Foundation for the various services it would render, were held to be ample to keep the establishment going. Its main function, as already implied, would be social and industrial research, in no wise competing with existing technical or scientific research institutions. Special care was exercised in the appointment of the first director, in March 1942, and the choice fell on Dr. Lawrence W. Bass, who has had wide experience both in the Mellon and in the Rockefeller Institutes. On the New England "Research Day" held in Boston during May 1942, Dr. Bass emphasized the need for technical excellence as the New England slogan, achieved through the sheer power of intelligence in manufacturing operations exercised through labour, management and research.

THE FOREST RESEARCH INSTITUTE, DEHRA DUN

IN a Dispatch of the Governor-General in Council, India (dated Nov. 1, 1862), which merits a closer study than some parts of the Empire and Commonwealth appear to have given it, the formation of an Indian Forest Service with an inspector-general of forests at its head as adviser to the Governor-General was advocated, in order to check the excessive exploitment and waste of the forests of that country, which had been greatly intensified with the increased demand following the establishment of ordered rule, and to reserve and conserve selected forest areas. In sanctioning the proposals, the Secretary of State for India wrote that whereas capital expenditure might and would be justifiably spent in ameliorating ruined forests and in opening out inaccessible ones, he was assured that the work projected would result in a valuable forest estate accruing, which in due course, in addition to being of the greatest benefit to the people, would bring in an increasing revenue to the Government. This inspired prophecy was abundantly fulfilled.

Yet, something more than half a century later, so incalculable is the potential value of the great forest estate in India, that the Government of India wrote (to the Secretary of State), "the greater part of our Forest properties are undeveloped". The subject then in question was research and the Forest Research Institute at Dehra Dun. This was inaugurated in 1906, a research building erected and opened in 1912 and soon after came the War of 1914–18. Imports of many material products in common use in India came to an end, and the young Research Institute was called upon to investigate the possibility of replacing them with raw materials from the forests. The success achieved is common history. The second Dispatch, from which the above sentence is quoted, proceeds to point out that the existing research buildings were totally inadequate to the demands of the Institute and proposed, in addition to considerable increases of the research staff, the purchase of a site of 1,200 acres and the erection of a new Institute building, workshops, residencies, etc., at an estimated cost of close on a million pounds sterling. This great scheme was sanctioned by the Secretary of State, and the new Institute building was opened some seven years later by the Viceroy.

Once again war supervened ; and once again India was faced with a closure of imports and the necessity of falling back on her own resources. For the second time the Forest Research Institute, now immensely stronger, has proved able to give invaluable services.

A recent publication, "Forest Research in India and Burma, 1941–42. Part I. The Forest Research Institute" (Dehra Dun : Forest Research Institute, 1943. Pp. iv+151. 1*s* 11*d*.), summarizes some of the work carried out. "Even more than last year," says the writer, "the work of the Institute has been dictated by War, in fact in certain sections and branches practically all work on ordinary programmes has been suspended to deal with war research. Whilst the branches dealing with Sylviculture, Botany, Mycology, Chemistry and Entomology have only dealt, in most cases, more or less indirectly with war problems, though their assistance has been solicited on occasion, the brunt of the work has fallen, as was the case during the last War, on the Utilization Branch, which throughout has had to devote its whole time to war work."

During the year this branch has been continuously evolving substitutes for which there was a shortage for one reason or another as a result of the War. In conjunction with the Mechanical Section, the Wood Working Section has devoted its energies entirely to the demands of India and the Army. Containers of many types down to the ordinary pail, and for a variety of purposes, were constructed of plywood, on the basis of researches at the Institute, and were afterwards manufactured at factories. The Wood Technology Section spent the year identifying timbers mostly for the Army, but was also concerned with the selection of the right type of timber for aircraft. It also trained in timber identification sixty men of the Ordnance and Military Engineers Services Departments. Ammunition boxes, walnut wood for rifles and other researches were undertaken by the Timber Testing Section ; while the Seasoning Section advised on the installation of kilns in various parts of India and also developed a simple hot-air kiln for quickly completing the seasoning of partially air-dried half-wroughts for such material as tool helves, shuttles, bobbins, picker-arms, etc. Unseasoned wood is useless for many of these purposes. The Adhesives for Plywood investigations have been already alluded to (NATURE, Jan. 29, p. 144). The Paper Pulp Section continued to work throughout the year, guided to a large extent by the Advisory Committee of the Indian Paper Makers' Association, there being a general shortage of paper in the country.

Some interesting research in the Chemistry Branch, carried out owing to war shortage, included a simplified method of preparing ephedrine and its salts from Indian Ephedras. This has been started on a factory scale, so that ephedrine salts are now being produced to replace the imported article. Retorts have been installed, as a result of experimental work, for the large-scale distillation of chir (*Pinus longifolia*) tar ; the perfected process in these retorts will now yield products not only suitable for use in rope and rubber works but also for medicinal purposes. Tamarind seeds were shown to be a cheap source of pectin. A large amount of work was also carried out on charcoal for producer gas.

Truly has the great value and usefulness of her forests to India in times of stress, as in those of peace, justified the foresight of that Secretary of State in the distant days of 1862.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public.)*

Saturday, February 12

SHEFFIELD METALLURGICAL ASSOCIATION (at 198 West Street, Sheffield), at 2.30 p.m.—Dr. G. Jessop : "Some Electro-chemical Methods of Analysis".

Monday, February 14

FARMERS' CLUB (at the Royal Empire Society, Craven Street, London, W.C.2), at 2.30 p.m.—Mr. A. P. McDougall : "Increasing the Cattle Population".

ILLUMINATING ENGINEERING SOCIETY (at the Royal Institution, Albemarle Street, London, W.1), at 5 p.m.—Dr. H. Buckley : "Some 18th Century Contributions to Photometry and Illuminating Engineering".

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 5 p.m.—Major R. C. Farrow : "Surveys for Power in the Coast Range of British Columbia".

SOCIETY OF ENGINEERS (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 5 p.m.—Mr. Frank Parfett : Presidential Address.

ASSOCIATION OF AUSTRIAN ENGINEERS, CHEMISTS AND SCIENTIFIC WORKERS IN GREAT BRITAIN (at the Austrian Centre Swiss Cottage, 69 Eton Avenue, Hampstead, London, N.W.3), at 7.15 p.m.—Dr. E. Spencer : "Coal as a Source of Chemicals".

Tuesday, February 15

ROYAL SOCIETY OF ARTS (DOMINIONS AND COLONIES SECTION (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Sir Bernard Bourdillon, G.C.M.G.: "Nigeria To-day".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Dr. J. Ramsbottom: "Fungi and Modern Affairs", i. "Fungi as Food and Poison".*

INSTITUTION OF ELECTRICAL ENGINEERS (WIRELESS SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Discussion on "Recording and Reproduction of Sound" (to be opened by Dr. G. F. Dutton).

Wednesday, February 16

BRITISH PSYCHOLOGICAL SOCIETY (SOCIAL PSYCHOLOGY SECTION) (at Hastings Hall, Tavistock House, Tavistock Square, London, W.C.1), at 2 p.m.—Mr. H. J. Eysenck: "Three Methods for Studying National Differences in Sense of Humour"; Marie Jahoda: "Some Difficulties in Participant Observation"; Mr. Otto Friedmann: "Some Problems of Political Propaganda".

ROYAL SOCIETY OF MEDICINE (at 1 Wimpole Street, London, W.1), at 2 p.m.—Discussion on "The Limitations and Uses of the Comparative Method in Medicine", 3: "Nutrition and Endocrinology" (to be opened by Dr. H. H. Green and Dr. S. J. Folley).

NEWCOMEN SOCIETY (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Mr. Robert S Nilssen: "The Pioneer Period of the Development of the Arithmometer from Pascal, 1642, Polenie, Leibnitz and others up to 1821, when the first Commercial Machine was Manufactured by Charles X. Thomas of Colmar".*

SOCIETY OF CHEMICAL INDUSTRY (MICROBIOLOGICAL PANEL OF THE FOOD GROUP) (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Dr. T. F. West: "The Pyrethrins and the Role of Pyrethrum in the Anti-Pest Measures".

GEOLOGICAL SOCIETY OF LONDON (at Burlington House, Piccadilly, London, W.1), at 3 p.m.—Scientific Papers.

ROYAL INSTITUTE OF CHEMISTRY (LONDON AND SOUTH-EASTERN COUNTIES SECTION) (at 30 Russell Square, London, W.C.1), at 5 p.m.—Dr. B. A. Southgate: "Recent Advances in Treatment of Sewage and Trade Waste Waters".

BRITISH INSTITUTION OF RADIO ENGINEERS (at the Institution of Structural Engineers, 11 Upper Belgrave Street, London, S.W.1), at 6.30 p.m.—Discussion on "Television Standards" (to be opened by Mr. L. H. Bedford and Mr. W. A. Beatty).

Thursday, February 17

CHEMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Dr. A. J. Ewins, F.R.S.: "Chemotherapy in Tropical Medicine".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Sir Lawrence Bragg, F.R.S.: "The Strategy and Tactics of Crystal Structure Analysis by X-Rays".*

KING'S COLLEGE (in the Department of Electrical Engineering, Strand, London, W.C.2), at 3 p.m.—Mr. N. V. Castling: "Electrical Switchgear".*

INSTITUTION OF ELECTRICAL ENGINEERS (CAMBRIDGE WIRELESS GROUP) (in the Engineering Laboratories, The University, Cambridge), at 8 p.m.—Inaugural meeting. Mr. T. E. Goldup: "The General Aspects of Radio Engineering Progress".*

Friday, February 18

ASSOCIATION OF APPLIED BIOLOGISTS (at the London School of Hygiene and Tropical Medicine, Keppel Street, Gower Street, London, W.C.1), at 11.30 a.m.—Annual General Meeting. At 12 noon—Discussion on "The Organisation of the Agricultural and Horticultural Advisory Services in Great Britain, with Special Reference to the Recommendations in the Luxmoore Report" (to be opened by Prof. W. B. Brierley).

INSTITUTION OF MECHANICAL ENGINEERS (at Storey's Gate, St. James's Park, London, S.W.1), at 5 p.m.—Annual General Meeting. Mr. H. A. Hepburn: "Fencing of Dangerous Parts of Machinery".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5 p.m.—Miss Olga Tufnell: "The Wellcome-Marston Excavations at Lachish".*

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 5 p.m.—Mr. R. T. D. Fitzgerald: "Nigeria and Reactions to the War".

INSTITUTION OF ELECTRICAL ENGINEERS (MEASUREMENTS SECTION, joint meeting with the TRANSMISSION SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. L. B. S. Golds and Mr. C. L. Lipman: "A Modern Earth-Fault Relay Equipment for Use on Systems protected by Petersen Coils".

Saturday, February 19

BRITISH ASSOCIATION OF CHEMISTS (at the Café Royal, Regent Street, London, W.1), at 2.30 p.m.—Twenty-sixth Annual General Meeting.

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

ENGINEERING LECTURER (Ref. No. C.1997A), MATHEMATICS LECTURER (Ref. No. A.422A), PHYSICS LECTURER (Ref. No. A.423A), ASSISTANT MATHEMATICS AND PHYSICS LECTURER (Ref. No. A.424A), ENGINEERING INSTRUCTOR (Ref. No. O/N.391), and a DEMONSTRATOR to assist lecturers in class work generally (Ref. No. O/N.392), for the Technical School of a Government Department located in Surrey—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting the appropriate Ref. No.) (February 16).

MASTER FOR MATHEMATICS AND SCIENCE in the Junior Technical School—The Clerk to the Governors, North-East Essex Technical College and School of Art, Colchester (February 17).

MASTER OR MISTRESS TO TEACH BIOLOGY and assist with some ELEMENTARY SCIENCE OR MATHEMATICS—Mr. E. B. Stockdale, Education Office, Mexborough, Yorks. (February 19).

WATER ENGINEER AND MANAGER of the Corporation of Dundee Water Department—The Town Clerk, City Chambers, Dundee (February 19).

TEACHER OF ELECTRICAL ENGINEERING SUBJECTS, and a TEACHER OF MECHANICAL ENGINEERING SUBJECTS, at the Smethwick Municipal College—The Chief Education Officer, Education Offices, 215 High Street, Smethwick 41 (February 21).

CHAIR OF BOTANY tenable at King's College, and CHAIR OF BOTANY tenable at Birkbeck College—The Academic Registrar, University of London, c/o Richmond College, Richmond, Surrey (February 21).

ASSISTANT ENGINEER for the Sudan Government Railways—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. E.783A) (February 23).

FIRST-CLASS MECHANICAL AND ELECTRICAL ENGINEER to act in the capacity of Plant Manager or Works Engineer (headquarters in the London area)—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No C.2025XA) (February 23).

LECTURER IN CHEMISTRY FOR MEDICAL STUDENTS—The Acting Secretary, University Court, Glasgow (February 25).

DIRECTOR OF THE IMPERIAL AGRICULTURAL RESEARCH INSTITUTE, Government of India—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C. (quoting Reference No. O.N.F. 2080A) (March 1).

UNIVERSITY CHAIR OF ANATOMY tenable at St. Mary's Hospital Medical School—The Academic Registrar, University of London, c/o Richmond College, Richmond, Surrey (March 20).

PROFESSORSHIP OF ENGINEERING SCIENCE—The Registrar, University Registry, Oxford (April 30).

DIRECTOR OF THE INSTITUTE OF MEDICAL AND VETERINARY SCIENCE, Adelaide—The Agent-General and Trade Commissioner for South Australia, South Australia House, Marble Arch, London, W.1 (May 31).

LECTURER IN PHYSICS (man or woman, honours graduate)—The Secretary, Woolwich Polytechnic, Woolwich, London, S.E.18.

WORKS MANAGER for Heavy Engineering firm in West Scotland—The Ministry of Labour and National Service, Appointments Office, 52 Robertson Street, Glasgow, C2 (quoting Reference No. 1105).

ASSISTANT MASTER FOR ENGINEERING SUBJECTS—The Principal, Technical Institute, Gravesend.

LECTURER IN GARDENING for Edgehill and Bingley Training Colleges—The Principals, at the Training College, Bingley, Yorks.

ASSISTANT LECTURER (temporary) in AGRICULTURAL CHEMISTRY—The Registrar, The University, Reading.

LIBRARY RESOURCES OF GREAT BRITAIN

AN important chapter in the McColvin report on the Public Library System of Great Britain dealing with co-operation, specialization and national projects emphasized the urgent need for a thorough and realistic survey of the whole field of special and non-public libraries. Such a survey, Mr. McColvin urged, would disclose a wealth of material which is not fully recognized and utilized, and would stimulate co-operation both between non-public libraries themselves and between non-public and public libraries. It is a necessary preliminary to a sound organization and development of the specialized resources of the nation.

This view was endorsed at subsequent discussions on the rehabilitation of European special library and information services during the Conference last September of the Association of Special Libraries and Information Bureaux, and the importance of such a survey has since been urged by Mr. G. Woledge, librarian of Queen's University, Belfast (see NATURE, Dec. 11, p. 687). A good deal of attention is being given to this question by the University and Research Section of the Library Association, which is considering the publication of a report on the post-war development of university and research libraries as a complement to the McColvin Report. The rehabilitation position, coupled with the problem which may well confront all libraries in completing after the War their broken and interrupted series of scientific and technical periodicals, will certainly enforce some attempt to plan systematically the distribution of available resources. Moreover, without some measure of co-operation, any efficient distribution of the book resources of Great Britain in view of present publishing difficulties is well-nigh impossible.

The basis for any such efforts must clearly be a survey of existing collections in all forms of special libraries, within and without the public library system of Great Britain, the functions they serve and their relation to the general needs of the country. The first step before any such inquiry can well be initiated is clearly to determine its scope, and on this point discussion of the proposal can most profitably at present settle. In such discussion, however, it is necessary to have a clear idea of the nature and extent of existing university and research libraries, their resources and the services they render, the form of present library co-operation, and the needs of the users of such libraries and the services they are entitled to expect.

In regard to the last, Mr. Woledge has already indicated some essential points. In an adequate system, both special libraries and special collections in general libraries will be required ; also reference collections and collections for loan. The geographical accessibility of reference collections must be considered, and the provision of the shelf access which is more easily supplied in a separately organized special library or department than in a section of a general library. Again, in addition to shelf-arrangements

which facilitate 'browsing', the collection and arrangement of ancillary material such as cuttings, off-prints, photographs, with all that is implied therein in the way of expert and specialized staff, must receive attention. Whether regarded from the point of view of an information system, the stimulation of creative thought or general education, the system must provide for the needs of the general reader as well as the specialist and research worker.

It is not, of course, suggested that the university and research libraries of Great Britain are not already, in themselves and through the system of voluntary co-operation developed in the last twenty-five years, already making most valuable contributions in such ways in supplying the material required for the advancement of knowledge. The problem is to determine whether the present extremely heterogeneous units, differing widely in age and size, could be knit to the general advantage into some more formal or informal structure. That need not affect the independent status of the individual libraries, to which some will attribute much of their present sense of responsibility, or the voluntary character of the existing system of co-operation. Under present conditions the individual libraries can scarcely continue to render the most efficient service to their own special clientele, and expend to the best advantage their available resources, unless regard is had to their position in the national system and the help which they might receive from, and give to, other libraries.

The university libraries are the properties of the bodies they exist to serve, and the interests of those bodies have naturally a first claim on their services. Almost without exception, however, they have recognized that part of the service which a university owes to its community is to make available, within the limits of its means and to those qualified to make use of them, such of its resources as are not available elsewhere and are not needed for its daily work. They have been glad to welcome outside readers and to lend their books to other libraries, and the contribution thus made to the advancement of knowledge is by no means insignificant.

The so-called 'special' libraries are also the property of various kinds of corporate bodies—local and national learned, scientific and professional societies, government departments, research associations, industrial and commercial firms, newspapers, etc. Although such libraries need feel even less obligation than the university libraries to the general public, their resources have been increasingly made available, if not generally, at least to other libraries whether special or public. Frequently they are the only source of supply of much specialized literature, and their co-operation in the national organization for inter-library lending through the National Central Library has been far more important than any statistics could show.

Besides these, there is a further group of government libraries the primary obligations of which are to the public in general; it should be unnecessary to say anything here about the importance of the British Museum as a reference library, or of the Science Library as a source of scientific periodicals for loan. The great municipal reference libraries, although in most ways associated more closely with the work of the public lending libraries than with that of other research libraries, are none the less an important part of the country's resources for research, and beside all these groups there is the National Central Library the organizing work of which has facilitated the full utilization of their resources.

No organization which leaves any of these groups out of account can claim to make anything like full use of Great Britain's library resources. A national scheme must provide for their voluntary participation on a national as well as on a local and regional basis. Given such co-operation, there should be no inherent difficulty in the allocation of public funds to provide for the strengthening or maintenance of any particular special collection which might be desirable in the public interest as a result of the proposed survey.

Without minimizing the importance of adequate staffing and housing of libraries, both special and general collections, or of efficient administration, the most urgent need is that of a survey of actual book resources as a basis for framing policy. An administrative survey is undoubtedly needed, but whether it should, as Mr. McColvin appears to imply, be combined with the urgently needed survey of the contents of libraries, may be questioned. Both are large projects, but they demand different qualifications in those responsible for carrying out the survey. Administrative reform, it is true, might sometimes be required before a special library could co-operate effectively, but that can scarcely apply to the appraisement of its holdings in the survey.

Much material for the survey of book resources in Great Britain is no doubt already in the possession of the National Central Library and of the Association of Special Libraries and Information Bureaux. The co-operation of both these bodies may be expected, but most of the present material will require re-examination. It is not enough in framing a policy merely to know of the existence of a special collection; information as to how far it is complete, how fully it is kept up to date, how far books are available for loan and in non-lending collections, and how adequately it is organized, is essential. The survey should bring out the weaknesses as well as the strength of the book resources of Great Britain.

There are other questions as to the extent of the survey which require determination. One is the inclusion or exclusion of local collections, most of which form part of the public library service and often in very small libraries. It may well be decid to leave manuscripts and theses to a subseque survey. Questions with regard to periodicals will probably arise, and the survey can be no more than a first step in the co-operative selection of periodicals, though it should assist the allocation of 'runs' where insufficient copies are available.

On the basis of such a survey, it should be possible to frame a policy which could be based on agreed principles, and to decide which collections could be most profitably developed in general and on what

lines. It would enable libraries to plan the development of their special collections, and though much more will remain to be done, such a survey is almost an essential preliminary to the co-operative purchase of periodicals.

The first objective in such a policy must clearly be the establishment of one full collection in a single library, such as is provided for many subjects by the British Museum and other great general libraries. No system of inter-library lending can take the place, for certain types of research, of a library where any reasonable demand can be satisfied at short notice. It is best that such a library should not lend its books, or at least do so sparingly, but Mr. F. C. Francis's paper on the British Museum as a special library, read at the autumn conference of the Association of Special Libraries and Information Bureaux, gives some idea of the problems that must be faced in attaining even this objective. We cannot assess the value and completeness of special libraries for this purpose without regard to the amount of material contained in more general works or series.

On the other hand, it is not so essential that the second objective, a full collection of books available for inter-library loan, should be in one library. Further development of the co-operation in this field which has been so marked in the last twenty years may be expected, chiefly on the lines of further specialization related to individual and to general needs, in the medium-sized general libraries, mainly reference libraries and university libraries. It may well prove that the greatest need for financial assistance is in this field.

The third objective should be a full collection, which may or may not be identical with one of the collections already mentioned, allowing access to the shelves and suitably arranged for that purpose. The importance of open-shelf libraries properly arranged so as to provide for and even encourage 'browsing' is often overlooked. The value of such 'browsing' in stimulating thought during research has been repeatedly demonstrated, and the special libraries and information departments might consider whether the re-arrangement of their material so as to permit free access to public material at least on the part of their own staff would not be worth while. Apart from that internal advantage, it might facilitate fuller participation in inter-library lending, though as Mr. McColvin has emphasized in his report, one of the objectives of a carefully planned policy should be to provide books where they are most wanted and thus reduce inter-library loans to a minimum.

The mere size of the great general libraries of Great Britain tends to preclude the supervision and shelf-arrangement necessary for open access collections of this type, and this function may fall to the special libraries or information departments. Again, every subject needs the provision of books in each of these three ways, though the relative importance will vary from subject to subject. For some subjects, more than one full non-lending collection may be required; overlapping or duplication must be considered in no narrow spirit. Questions of local as opposed to national book provision would rightly be disregarded by the survey, which none the less must examine the desirability of ensuring that certain large classes of literature, which cannot, and should not, be repeated in all libraries, exist in duplicate or triplicate for inter-library loan.

If any such survey is to be initiated in time for its results to be available when the replanning of libraries and replenishment of stocks become possible, it is imperative that it should be set on foot without undue delay. As a first step, the question of the scope of the inquiry and survey requires immediate consideration, and in this the views not only of librarians but also of users of libraries are alike important. The goodwill of all concerned in furthering the co-operation, which has been such a feature of the inter-war period, and in building up a network of special libraries and special collections in general libraries so as to cover the whole field of knowledge, or in the co-operative collection so far as possible of particular items such as periodicals, will be essential. Nor should its importance be overlooked by scientific institutions, to whom the housing of their existing libraries, as Sir Henry Dale indicated in his presidential address to the Royal Society, is already a matter of concern, and it should be assured of the warm support of all those who recognize that plans for the expansion of the universities must include generous provision for the libraries, both books and buildings.

AN INTERNATIONAL LANGUAGE

(1) Basic English and Its Uses

By I. A. Richards. Pp. 127. (London: Kegan Paul and Co. Ltd., 1943.) 3*s*. 6*d*. net.

(2) Basic for Science

By C. K. Ogden. (Psyche Miniatures, General Series No. 95.) Pp. ix+314. (London: Kegan Paul and Co. Ltd., 1942.) 3*s*. 6*d*. net.

LAST September, when Mr. Winston Churchill received an honorary degree from the oldest of American universities, he spoke of the common task awaiting our two peoples in the service of mankind. Himself the son of an English father and an American mother, and a supreme master of our common tongue, he did not see why we should not try to spread the use of our language even more widely over the globe. He went on:

"Some months ago I persuaded the British Cabinet to set up a Committee of Ministers to study and report on Basic English. Here you have a plan. There are others, but here you have a carefully wrought plan for an international language capable of very wide transactions of practical business and of interchange of ideas. . . . What was my delight when, the other evening, quite unexpectedly, I heard the President of the United States suddenly speak of the merits of Basic English . . . Harvard has done more than any other American university to promote the extension of Basic English. The first work on Basic English was written by two Englishmen, Ivor Richards, now of Harvard, and Ogden, of Cambridge University, England, working in association."

The latest works by Ivor Richards and C. K

Ogden treat of the uses of Basic English for the advancement of science. This is indeed the main theme of Mr. Ogden's book, which is written in Basic. Dr. Richards' volume has a wider scope. Like Mr. Churchill in his Harvard speech, Dr. Richards is chiefly concerned with the world's need of some means of international communication for the transaction of practical business, the interchange of ideas, and the spread of normal English. He argues with much force that national aggression is the outcome of spiritual separation, because sentiments of exclusive loyalty to the group, or of disloyalty to the planet, plunge us into wars; that the need for a common language will be greater than ever when the post-war world is linked up by the aeroplanes of to-morrow, by world-wide controls of many kinds—sanitary, economic, commercial—and by a universal demand for information and news; and that a world inevitably made one by its physical communications will destroy itself unless it can be united also through intellectual and moral communications.

If, then, in addition to its national tongues and its local vernaculars, the post-war world is going to need some common means of international communication, what is it to be? Dr. Richards gives his reasons for believing that no artificial language will meet the case and concludes that, "If there is to be a common language it must be a simplified, but not denatured, form of one of the world's existing major languages". Dr. Richards examines the question which of these languages is best suited to the task. He decides in favour of English, not merely because it is most widely used already, but also because there are good reasons for its prevalence. For example, despite the handicap of its appalling spelling, it can be made easier than any other language for learners in general.

The work on Basic English begun by Ogden and Richards in Cambridge during the 1920's and continued in many countries—particularly in the United States with the help of the Rockefeller Foundation—has aimed at discovering how English may best be learnt through a limited vocabulary in such a way that, if the process is interrupted at an early stage, the work already done may provide an auxiliary means of international communication of very wide use, and so that, if the learning is continued beyond that stage, there will be nothing to unlearn.

This "Basic English is English made simple by limiting the number of its words to 850 and by cutting down the rules for using them to the smallest necessary for the clear statement of ideas. And this is done without change in the normal order and behaviour of these words in everyday English. This is the first point to make clear. Basic English, though it has only 850 words, is still normal English. It is limited in its words and its rules, but it keeps to the regular forms of English. And though it is designed to give the learner as little trouble as possible, it is no more strange to the eyes of my readers than these lines", by Dr. Richards, "which are in fact in Basic English".

Much of Dr. Richards' book is concerned with the teaching of English to foreigners, particularly in China, with Basic as the first stage of the process. While insisting that Basic is no adequate substitute for a mastery of literary English, he holds that a sound knowledge of it is a better and more attainable goal than a more impressive programme that, in fact, leaves many a student without any serviceable command of the language. He adds that anyone whose native language is English will find that a few hours' study and practice are enough to enable him to travel, shop, visit and do the daily routine of business in Basic.

Dr. Richards found that, in China, the main incentive to learn English is interest in what is most distinctive about the West, its science. Much of the language of science is already international. Basic seeks to fill the gaps. A beginning has been made with a "Basic Science Library, a programme of science in Basic designed for the general reader, the learner of English, and the teaching of science in schools".

Mr. Ogden's little volume, "Basic for Science", gives many examples of the uses of Basic for popular exposition—including a fascinating extract from J. B. S. Haldane's writings on the sizes of animals—as well as for abstracts of original research. It is to be hoped that it may soon become the general practice for research abstracts to be written in Basic so that they may be more widely read all over the world. Meanwhile, Mr. Ogden's book provides scientific workers with an invaluable model for writing their papers and presenting their results in Basic English.

MAXWELL GARNETT.

HISTORICAL ANALYSIS OF ARCHÆOLOGICAL METHOD

The Three Ages

An Essay on Archæological Method. By Dr. Glyn E. Daniel. Pp. 60. (Cambridge: At the University Press, 1943.) 3*s*. 6*d*. net.

THIS concise, learned but lucid memoir deserves study not only by all archæologists, but especially by other men of science who have occasion to refer to archæological results but normally consult those large text-books that use the three-age system in the old misleading manner. It is really a critical historical analysis of archæological method, written by a representative of the brilliant younger generation of prehistorians now on active service. The author brings out ten important points.

(1) A workable system of classification being the indispensable condition for reducing any branch of empirical knowledge to a science, the adoption about 1818 by C. J. Thomsen of Copenhagen of the division into Stone, Bronze and Iron Ages marks the beginning of scientific archæology. (2) Thomsen adopted this system for the arrangement of museum specimens collected in a single geographical province, Denmark, and (3) on the strength of empirical observation, not of *a priori* theories. (4) Since its publication in 1836 it has been found, again empirically, applicable to material from other regions, but *only in Europe, the Near East, and Asia*. (5) With the accumulation of material it became possible and necessary to subdivide the Ages; the Stone Age has been split into Palæolithic and Neolithic since 1865, and these and the remaining Ages have since been subdivided in their turn. To these smaller subdivisions early investigators, following geological precedents (for example, Cambrian), gave names derived from type sites; de Mortillet's terms—Chellean, Acheulian, etc.—and Tischler's—Hallstatt and La Tène—are still occasionally used for such subdivisions of the Palæolithic and Iron Ages respectively, with confusing consequences. For (6) even within, say, the Stone Age of so small an

area as France or Denmark we have now to recognize a plurality of distinct but parallel and contemporary 'cultures' here defined as "significant and persistent associated assemblages of artefacts".

(7) The progress of prehistory has been retarded by the accident that the same names or the same sort of names (for example, Aurignacian, Hallstatt) have been given to assemblages of both types. In reality, the concept of 'culture' introduced a basis of classification quite distinct from the serial or chronological one underlying Thomsen's scheme; for the association of artefacts is due not only as in the latter to contemporary use, but rather to sociological, economic and in a word historical factors. (8) The three-age scheme was put forward as representing, and stratigraphically proved to represent, a chronological succession of technological stages in Denmark's prehistory. Less modest and less intelligent disciples took Thomsen's Ages as equivalent to periods of absolute time like the eras of geology. It has cost a lot of trouble to get rid of this erroneous deduction.

(9) To correct such abuses Daniel proposes some very reasonable and hopeful changes in classificatory terminology: (*a*) Names from type sites (Acheulian, La Tène) or even derived from type objects (like "Separate Grave"—his other examples, Chatelperronian and Gravettian, are in fact derived from French sites) should be reserved for the cultural classification (point 6). (*b*) Position in the serial classification, relative or absolute chronology, should be denoted by numbers or letters; in a footnote the author instances the use of numbered 'periods' in my "Prehistoric Communities of the British Isles", published since the memoir was written. He very properly condemns the practice of two of his most brilliant contemporaries who use terms like 'Neolithic A' and 'Iron Age B' to denote cultures without exclusively serial connotation. His complaint that Clark uses "Mesolithic I" where he should write "Holocene I" is, however less legitimate, since "Holocene I" should be applicable to the whole world, while Clark's division purports to apply only to Northern Europe. Prehistory is likely to be burdened for a long time with purely local sequences that must be distinguished by some qualifying adjective quite free from any suggestion of œcumenical significance.

(10) As a consequence, Thomsen's scheme can now be abandoned. It provided an indispensable scaffolding, but now distorts the structure. To be scientifically valid, a classification must use features that are not only well defined and easily recognized, but also significant and symptomatic of wider relations. The author sympathetically reviews recent attempts to give stadial significance to the Ages by equating them with decisive stages in the economic development of societies. The equations of the Palæolithic and Mesolithic Ages on one hand, and the Neolithic on the other, with the food-gathering and food-producing economies respectively of Elliot Smith would, he admits, achieve this result; but some food-gatherers, around the east Baltic for example, used a formally Neolithic equipment of polished axes, pottery, etc. My own attempts to give a comparable economic significance to the Bronze and Iron Ages are rejected. The urban revolution leading to civilization does not, of course, coincide with either of these Ages. But elsewhere I hope to have opportunity to set forth the concrete evidence that induces me still to maintain that the regular use of cast copper or bronze, and afterwards the substitution therefor of cheaper iron, had such far-reaching technological, economic and sociological consequences that they must rank as defining really distinctive stages in the development of even barbarian societies. Daniel himself suggests that a more significant division would be to bracket the Neolithic and Early to Middle Bronze Ages together as an "Eochalcic Age", and to let a "Full Metal Age" begin with the Late Bronze Age and extend over the whole prehistoric Iron Age. This scheme has the advantage of giving due prominence to the remarkable but still unexplained cheapening of bronze that distinguishes the Late Bronze Age and its results; for neither this fact nor its implications had previously been given adequate recognition. But I shall show elsewhere that its technological and social repercussions were not of comparable magnitude to those following the development of iron working. Incidentally, the term "Full Metal Age" has already been reserved to designate an earlier technological stage that in some regions—in the Wessex culture, for example—is of considerable significance. Nevertheless, I believe that for the presentation and exhibition of archæological results, a scheme on the lines outlined under (9) by Daniel will prove more fruitful than any rationalization of Thomsen's trinity.

A Challenge to Scholarship
By W. Mansfield Clark. (University of Pennsylvania Bicentennial Conference.) (University of Pennsylvania Press.)

THE first item in the above list recalls the interesting fortunes of the word 'philosophy'—originally the love of wisdom, and the search for causes of all things in heaven and earth. In course of time a distinction was made between natural and moral philosophy, but the old meaning still survives, for example, in the degree of doctor of philosophy. The Royal Society of London, founded in 1660, essentially scientific in its outlook, has ever been famous for its *Philosophical Transactions*, which are records of scientific investigations. The American Philosophical Society was founded at Philadelphia by Benjamin Franklin in 1743. It had little or nothing to do with philosophy as we now understand the term. Its interests lay in new discoveries in what we now call the sciences, in "all philosophic [that is, scientific] experiments that let light into the nature of things, tend to increase the power of man over

matter, and multiply the conveniences and pleasures of life". It was the parent of the American Association for the Advancement of Science, founded in 1840. Since the organization of the latter, the American Philosophical Society has become a local scientific association for Philadelphia. But though a local association, it is broad in its outlook, as its latest *Proceedings* show. Not only does it deal with the part played by the Society in the world of science, and in the development of American education, but also with American contributions to historiography, linguistics, economics, anthropology, archæology and architecture. These *Proceedings* are a most interesting record of a few of America's past achievements in science.

As its title indicates, "Twentieth Century Philosophy" is essentially a book of the day. It is a symposium containing twenty-two chapters, either directly contributed by eminent thinkers and scholars, or otherwise representing their positions. One does not wonder that the editor has found it difficult to bring together under one cover thinkers of such divergent principles and temper, and that, having let each of them state his case, he leaves it to the reader to draw his own conclusions. Among the contributors we note the names of J. H. Tufts, Whitehead, Russell, Dewey and Santayana, and among the chapters of special interest to the man of science we note those on the philosophy of science, logical empiricism, the stories of American realism and pragmatism, philosophic naturalism, and the dialectical materialism emanating from the U.S.S R. The whole forms a useful compendium of living, and warmly contending, schools of thought. If it is the business of each thinking man, whether American or not, to make his own philosophy, his own general outlook upon the universe, this book will help him in his quest, and may help him to understand and tolerate systems which he rejects.

We turn to a topic of wider appeal to readers of this journal—that of the encouragement of research. The liberal provision made for research in the United States is well known in Britain, and indeed Britain has had the advantage of sharing in that liberality. The way they do such things in the United States is exemplified by the extensive bibliography of research studies in education 1939–40, recently issued by the U.S. Office of Education. The book contains 4,012 entries of theses and studies reported by 133 places of education, mostly universities and teachers' colleges, and a few technical institutes. An analysis shows 674 doctors' dissertations, 3,183 masters' theses, and 155 studies reported as faculty research.

In an important sense the figures are revealing. We may assume that the studies reported by faculty members are real contributions to knowledge, and that as a rule, though in a less degree, the same may be said of the doctors' dissertations. There remain the masters' theses, written for the master's degree, and constituting no less than three fourths of the impressive total. Their object is to ensure that a person who has shone sufficiently in his 'recitations' at school, and has attended the appointed lectures at college, shall give evidence of ability to do a piece of independent work. Usually it consists of a few score pages of typescript on a local theme, such as a survey of education in a certain county of the State, or "the effect of the use of separate answer-sheets on reading test results", or "a study of family life in its relation to education in the second grade" of a certain school. There is no question as to the value of these theses for the writers' own education. Only in an elementary sense, however, can they be called contributions to new knowledge. They exemplify a principle now recognized as vital in all progressive schools, both in the United States and in Britain. It is worth recording that in Victorian England the way was led by eminent teachers of science, such as L. C. Miall of Leeds and Lloyd Morgan of Bristol, who emphasized the difference between finding out and being told, and thereby led teachers to realize that pupils from an early age may be led into the paths of simple research.

To return to the question of research in the higher sense. There is no need to emphasize its value, for it is recognized as the life-blood of science. There is, however, a correlative truth which is apt to be lost sight of, and which was forcibly brought out in an address entitled "A Challenge to Scholarship" delivered at the bicentennial conference of the University of Pennsylvania by Dr. Mansfield Clark, professor of physiological chemistry in the Medical School of Johns Hopkins University. He shows how American teachers imported from Europe not only the scientific ideal of research, but along with it the philosophic ideal of an organized system of thought. Undoubtedly, he says, we have added much of our own that is good, but "what needs examination is the tendency in scientific circles to enthuse over research alone". He recalls that in 1896 Merz, in his "History of European Thought in the 19th Century", gave warning of the decay of the ideal of *Wissenschaft*, "a decay that someone put tersely when he remarked that the German scholars had got into the habit of going down deeper, staying down longer, and coming up muddier, than any other". In the United States, says Dr. Clark, the danger that threatens education in the sciences is in "the crumbling of the ideal that a goodly part of scholarship is the studious maintenance of balance between the advancement of knowledge and its consolidation". One realizes his meaning when he adds incidentally that "the last decennial index to *Chemical Abstracts* contains about two million entries !"

In conclusion, it is interesting to observe how the ideal of research has fared in another great country which has temporarily fallen on evil days. At a conference held in May last by the Association of University Professors of Allied Countries in Great Britain ("The Function of a University in a Modern Community." Pp. 57. (Oxford: Basil Blackwell. 1*s*.)), Prof. Paul Vaucher noted among the distinctive features of French universities the importance attached to a high standard of general culture—an ideal which dominated university organization. During the last forty years, however, profound changes have taken place, as the organization "was not well suited to promote scientific research or to provide for students a proper training in research". Hence the development of laboratories in the faculties of science and medicine, and of seminars in the faculty of arts. "Individual scholars, disregarding the critics who often accused them of being under German influence, started creating centres for collective research and for common training in research."

So we are reminded that, whether in the United States or Britain or France or Germany, the scholar and the scientific worker as such are simple seekers after the truth, the whole truth, and nothing but the truth. T. RAYMONT.

SCOPE AND LIMITATIONS OF INFRA-RED MEASUREMENTS IN CHEMISTRY*

By Dr. H. W. THOMPSON
University of Oxford

FOR some years infra-red spectroscopy has been a valuable research tool in pure chemistry, particularly in problems of molecular structure and the deduction of molecular data. Its value in industrial work, both for routine and research measurements, is now becoming fully appreciated, and its usefulness in general organic chemistry may soon at least equal that of ultra-violet spectroscopy. It is therefore opportune to consider its uses and limitations.

The infra-red may be said to extend between wave-lengths of about 1 μ and 10^4 μ. This corresponds to a range of frequencies 3×10^{14} to 3×10^{10} per second, or 10^4 to 1 wave numbers. A small region from the visible up to 1·2 μ can be studied photographically, using conventional spectrographs with glass prisms or finely ruled diffraction gratings. Between 1 μ and 25 μ, prism spectrometers are most often used, in which the prism is made of quartz, fluorite, rock salt or potassium halides. Since large natural crystals of these materials are growing scarce, their production recently in large blocks by cooling the molten salts is important. Diffraction gratings have to be used at wave-lengths beyond 25 μ, although they are also used at shorter wave-lengths if higher resolving power is required. In order to obtain a greater concentration of energy and avoid its dissipation among many spectral orders, these 'echelette' gratings are ruled with specially shaped grooves so that reflexion occurs at favoured angles. The infra-red radiation is usually detected by means of thermo-electric devices. Striking advances have recently been made by the development of very sensitive vacuum thermocouples and voltage amplifiers, thus leading to an increase in both sensitivity and stability of the galvanometric systems, and to the construction of automatically recording spectrometers. In this way, infra-red technique has ceased to be a delicate research method and has become more easily applicable by non-specialists.

Infra-red emission spectra are rarely intense enough for measurement, and we are nearly always concerned with the absorption spectra. In this spectral range, the quanta of energy absorbed cause the molecules to rotate and vibrate. In order to absorb rotational quanta, a molecule must have a permanent dipole moment. Vibrational quanta are absorbed if the particular vibration involves a changing molecular dipole moment. Thus, although homonuclear molecules like hydrogen or nitrogen do not absorb vibrational quanta, methane can do so, since it can perform an unsymmetrical nuclear vibration which produces an electric moment.

Rotational quanta are nearly always small, and the pure rotational spectra therefore lie at very long wave-lengths, between about 10^2 μ and 10^4 μ, or 1–100 wave numbers. Little is so far known about them, mainly owing to technical difficulties in studying this region, but also because of their complexity with all except diatomic molecules. In the latter case, the spacing between rotational lines leads to the molecular moment of inertia and hence to the bond-length.

Vibrational quanta are larger, the fundamentals varying from about 100 cm.$^{-1}$ to 4,000 cm.$^{-1}$. The fundamentals, lower harmonics, and combinations are therefore absorbed between about 100 μ and 1 μ. Changes in rotational energy usually accompany the absorption of vibrational quanta, and with gases or vapours this gives rise to a fine structure of the vibration bands, the precise details of which are of great significance. With liquids and solutions, the intermolecular influences lead to the disappearance of this rotational structure.

A rigid non-linear molecule has $(3n-6)$ normal vibrations, and a linear molecule $(3n-5)$. With simple symmetrical molecules like carbon dioxide, water or ethylene, it is possible to specify in a general way the geometrical form of these vibrations. They can sometimes be described as 'breathing', 'rocking', 'bending' or 'twisting' motions, and it is also sometimes convenient to differentiate between valency vibrations and deformational modes according as the motions of nuclei are along or perpendicular to the valency bonds. If a molecule has some degree of symmetry, its vibrations can also be characterized with reference to each element of symmetry, and by the way in which the electric moment changes with reference to these symmetry axes. Thus, the 'breathing' vibration of carbon dioxide is symmetrical with respect to the centre of symmetry—the carbon atom; and the other stretching vibration is antisymmetrical. In the latter case, the change of electric moment occurs in a direction parallel to the molecular axis, which is an axis of symmetry; in the deformational mode of carbon dioxide, however, the change in moment is perpendicular to the molecular axis. When the molecule has several planes, or other elements of symmetry, a given vibration may be symmetrical or antisymmetrical with respect to each. In the same way the total change in electric moment in different vibrations will vary in magnitude and in direction with respect to the symmetry elements. Some vibrations, for example, the totally symmetrical modes of ethylene, will involve no change in electric moment, and will not be absorbed as fundamentals in the infra-red. In other cases, the intensities of absorption will vary as the position-rate of change of electric moment during the vibration. For these reasons, intensities, taken alone, are no rigid guide in the allocation of observed frequencies to the fundamental modes. Many semi-empirical rules have to be applied, such as the persistence of some magnitudes through a related series of compounds, the fact that motions of lighter nuclei will usually have higher frequencies than those of heavier ones, and the comparison of spectra of isotopic molecules, particularly those containing hydrogen and deuterium.

For certain purposes, a correct assignment of the fundamental frequencies is essential. The Raman spectrum provides valuable additional data. Here, vibrations are active if they involve a changing molecular polarizability. It therefore happens that frequencies which are not found in the infra-red spectrum may appear in the Raman spectrum, and vice versa. Raman frequencies also differ in their degree of polarization, which may enable us to allocate them more precisely to different types of vibration. Some oscillations, such as the twisting mode of ethylene, are inactive in both Raman and infra-red spectrum. These can sometimes be determined from fluorescence data, or from a comparison

* Substance of the Tilden Lecture, delivered before the Chemical Society on January 20.

of the measured specific heat with that calculated statistically using all the known frequencies.

The other important guide in assigning the vibration frequencies is the analysis of the rotational structure of the infra-red absorption bands. If the molecule has some symmetry, this rotational structure differs according to the direction in which the electric moment changes with reference to the axes of symmetry. The differences are often so characteristic that inspection may serve to allocate the vibration to a particular symmetry class. Detailed analysis of the spacings between the rotational lines may simultaneously lead to the moments of inertia and hence to knowledge about the molecular structure, and much information about simple molecules obtained in this way is more accurate than by any other method.

Such rotational analyses are limited, however, to molecules which are (*a*) volatile enough to be studied as vapours, (*b*) small enough to have low moments of inertia and resolvable structure, and (*c*) have some symmetry. These restrictions are severe, and most molecules with which the chemist has to deal are excluded. Even if (*b*) and (*c*) do not apply, however, useful information can often be obtained. Thus, if there is some symmetry but the moments of inertia are large, the envelope of the rotational structure, or band contour, can be measured. This contour, like the rotational structure itself, varies characteristically with the direction in which the electric moment changes during the vibration with reference to the axis of symmetry. By measurement of the spacing between sub-maxima in the band contour, moments of inertia can be roughly determined or an assumed molecular structure confirmed. If the molecule is asymmetrical, the rotational fine structure of bands is very complex, and although this class of molecules includes such simple structures as water, hydrogen sulphide, ethylene, and formaldehyde, few satisfactory analyses have so far been achieved. Here again, some progress can be made by measuring the band contours. These differ according as the direction of change of electric moment is parallel to the least, middle or greatest axis of inertia. In practice, hybrid contours are to be expected, since the change of electric moment will have components along more than one of these axes; but in many cases the contours are surprisingly simple, and not only help in assigning the frequencies but also serve to confirm assumed molecular structures.

It must be emphasized that even when all three principal moments of inertia of a molecule are known, the whole structure often cannot be deduced, since there are more than three bond-lengths and angles. One or more of the latter must then be assumed in order to determine the others. When data are available for a series of related molecules such as the methyl halides, self-consistency in the whole group may be a useful guide. In other cases, comparison of isotopic molecules is valuable, particularly those containing hydrogen and deuterium.

Another serious difficulty in analysing rotational structures and contours results from perturbation of energy-levels due to interaction of vibration with rotation, which tends to be specific. On the other hand, incompletely resolved or partially unexplained rotational structures often serve to decide between alternative molecular configurations. In this way hydrogen peroxide has been shown to be non-planar, and formic acid to have a *cis* rather than *trans* structure.

When molecules are involatile, or large, only the vibration frequencies may be determinable. If all the frequencies are known, the specific heats can be calculated, using the results of statistical mechanics which relate them to the partition function. Discrepancies in some cases between the calculated and measured values have been correlated with the phenomenon of restricted rotation about bonds in organic molecules. Estimation of the potential energy barriers restricting such internal rotation in series of molecules have now been made and throw some light on the nature of the forces between non-bonded atoms in molecules. If in addition to the vibration frequencies, the moments of inertia are also known, the free energy and entropy can be calculated; and provided other thermochemical data are available, so that changes in zero-point energy can be calculated, equilibrium constants can be calculated for reactions where they cannot easily be measured.

If molecules are regarded as a system of mass points between which harmonic forces operate, it is possible to derive equations relating the vibration frequencies with the nuclear masses and force constants for stretching of bonds and bending of angles. Comparison of the force constant of the same linkage in different compounds will give a direct indication of the multiple or hybrid character of bonds. Interesting results have been obtained in this way for some relatively simple molecules. Progress is limited, however, not only by the severity of the computations required, but also by the more fundamental problem of selecting a valid function to express the variation of potential energy with nuclear configuration. Different types of force field have been assumed, and although no general rules can yet be laid down, the most satisfactory seems to be that which assumes in addition to valency forces certain interaction terms. Future progress must be guided by considering series of related molecules, and thus discovering which types of interaction are important.

As explained already, particular vibration frequencies will be permitted to appear either in the Raman spectrum or in the infra-red spectrum, in both, or in neither, according to the symmetry point group to which the molecule belongs. A comparison of the spectra may therefore fix the symmetry class, and hence decide between possible alternative molecular structures. Benzene and cyclohexane have been studied in this way. In the former case, the question is to decide whether the molecule has a centre of symmetry, which a resonance hybrid should show, but which the Kekulé structure does not have. In the latter case we have to decide between a planar, boat-shaped, or chair-shaped structure. Results are so far rather unconvincing, mainly because the Raman measurements are normally made with the liquids, where molecular distortions lead to a break-down of the selection rules.

Although any molecular vibration in reality involves the whole molecule, some linkages retain individuality and give rise to characteristic absorption frequencies. Such linkages can therefore be detected or estimated in molecules. The absence of the characteristic O–H group absorption in some hydroxy compounds has proved the existence of the hydrogen bond and revealed unexpected cases of inter- and intra-molecular association. The individuality of linkages tends to disappear when the nuclei are roughly equal in mass or the force constants roughly equal in value. In spite of this, some nuclear skeletons,

such as the nitro or tertiary butyl groups, retain characteristic sets of frequencies in different compounds. Deformational motions are also sometimes characteristic. For example, the symmetrical deformational frequency of the CH_3-group can be used to indicate its presence in polythene; and different types of olefine can be distinguished by differences in some of their deformational vibrations. The latter results can be used to study the cracking of hydrocarbons or the method of polymerization of unsaturated compounds. Thus, when 1.3 butadiene condenses to form buna rubber, the extent of 1.2 or 1.4 addition can be estimated. In polymeric chemistry a variety of problems can be tackled successfully, such as the arrangements within a long chain, or the structure of interpolymers.

Since no two molecules, except a pair of optical isomers, have the same nuclear configuration, the fact that any molecular vibration involves the entire molecule implies that no two molecules will have a completely identical set of vibration frequencies. The infra-red spectrum will therefore be a fingerprint of the molecule. On this basis, many mixtures, sometimes of great complexity and not susceptible to other methods, can be analysed. The method is particularly suitable for isomeric mixtures. Even stereoisomers show different spectra. Analyses of this kind are rapid and require a very small amount of material. Certain technical difficulties still exist, but are rapidly being overcome, and the method has wide applicability in organic chemistry. Accurate measurements on absorption intensities may also lead to more detailed knowledge about the nature of chemical bonds.

THE ANTIQUITY OF MAN IN AUSTRALIA

By PROF. F. WOOD JONES, F.R.S.
University of Manchester

A LARGE part of a recent Memoir of the National Museum, Melbourne (No. 13, 1943), is devoted to the question of the authentic antiquity of certain human artefacts and skeletal remains that have been recorded from various parts of Australia over a long series of years. The available evidence in relation to each find is carefully analysed, and a judicial summing up leads, in most cases, to a verdict of 'not proven'.

This new survey has been undertaken by the director of the Museum, Mr. D. J. Mahony, as a consequence of the recent discovery of mineralized human remains near Keilor at the junction of Dry Creek and the Maribyrnong River in the neighbourhood of Melbourne. The skull was unearthed from undisturbed strata 18 ft. below the surface. The district in which the find was made shows the presence of three distinct river terraces. The terrace from which the skull was excavated is the highest of the series and is 45 ft. above the adjacent river bed, the other terraces being respectively at the 36-ft. and 27-ft. levels. Mahony's conclusion from a geological survey of the area is that the terraces "represent the eustatic rise of sea level during the Riss-Würm interglacial phase" and that "the skull and the terrace are evidently contemporaneous". The correlation of the European Riss-Würm period with happenings in southern Australia and Tasmania is made in the assurance that "most glaciologists consider that glacial and interglacial phases were contemporaneous in both hemispheres".

The circumstances of the finding of the skull *in situ* in the undisturbed face of a sand-pit seem to be well authenticated. The skull itself is mineralized and bears every evidence of being contemporary with the stratum from which it was removed. We may therefore claim that the Keilor skull is the first Australian human fragment the geological antiquity of which is definitely guaranteed by the circumstances of its finding and that, in the opinion of competent Australian geologists, it dates from the Riss-Würm interglacial phase of the Pleistocene period. We may consider its geological story as settled, subject only to possible minor differences of opinion among experts concerning the precise age of the deposit in which the skull was found.

The study of the human remains is, however, far from being completed. In the introductory paper by Mr. Mahony, it is said that "Two mineralised human skulls and some other bones were found". The actual finder of the skull mentioned "one fossilised limb bone and several other fragments" as being with the skull. He adds that "since then five pieces of another skull were found at the same level and about 6 feet distant from the first skull". Only one skull (lacking the mandible) is in the possession of the National Museum, and it is the only specimen dealt with in this publication.

The account of the skull is written by Dr. J. Wunderly and that of the palate and maxillary teeth by Dr. W. Adam. Neither of these accounts can be considered as being definitive descriptions of the characters of the skeletal remains, and it might have been well to limit the account of the skull to a simple statement of its characters and to have refrained from any suggestions as to racial affinities until the rest of the skeletal remains were available for examination. Dr. Wunderly's conclusions concerning the skull are that "it combines Australoid and Tasmanoid characteristics in about equal proportions". Further, he states that "the Australoid and Tasmanoid anatomical characters are consistent with the theory that the Australians had a bi-racial origin, and also with the supplementary theory that Australia was originally peopled by Negritos. The presence of characteristics of the two racial types is more important than their proportional relationship". I find it difficult to understand the meaning of this last statement. Presumably it means that the Australian race as we know it is compounded of two primary races. But if Dr. Wunderly means that these two primary races were what we now know as Australians (Dravidian or Pre-Dravidian Cymotrichi) and Tasmanians (Oceanic Ulotrichi) is not clear, for the peopling of Australia by Negritos (presumably Tasmanians) he relegates to a "supplementary theory". Should he, in fact, mean that the Australian race is compounded of a Pleistocene Australian-Tasmanian mixture, he must be prepared to admit that the Tasmanian race is equally a mixture of the same two elements. For if that is not admitted, explanation is needed as to how, when Australian and Negrito (Tasmanian) had formed a mixed race in continental Australia in Pleistocene times, the Tasmanians, with all their racial characters intact, were present in Tasmania on the arrival of the white man. Only two possible explanations seem to present themselves. The first is that it so happened that the Ulotrichous Negritos who passed from Australia to Tasmania chanced, in

some extraordinary way, to have avoided this racial admixture with Australians during their occupation of Australia. The second, that the influx of Negritos into Australia was an event altogether separate from their advent into Tasmania: that there were two independent Negrito migrations, one into the mainland that merged its blood with that of the Australians, the other into Tasmania direct and not via continental Australia and so preserving their full Negrito characters. It cannot be claimed that either of these hypotheses tends to clarify the question of the peopling of the Southern Continent.

Concerning the palate, Dr. Adam concludes that "it is more Tasmanoid than Australoid" in certain features. One of these features is that "it is relatively broad like the Tasmanian palate; the Australian palate is relatively narrower". It is unfortunate that of the Tasmanian and Australian palates figured in Plate XI, that of the Australian would seem to be of a considerably higher relative broadness.

The question would seem to arise as to the possibility of any physical anthropologist sorting out the constituent racial elements present in any individual skull. Tables of figures of comparative measurements are impressive; but it would seem that they are incapable of solving the problem. Taking Dr. Wunderly's tables 1 and 2, in which he gives measurements for Australian, Tasmanian, Maori, Marquesan and Hawaiian skulls, it is at once apparent that it cannot be from these that he has drawn the conclusion that the Keilor skull is compounded of Australoid and Tasmanoid characteristics in about equal proportions. If the measurements of the Keilor skull are matched with the measurements given in the tables of the other skulls, it will be found that in fifty-seven instances they come nearest to those of Australians, in thirty to those of Maoris, in twenty-nine to those of Marquesans, in twenty-one to those of Tasmanians and in eighteen to those of Hawaiians. Surely this is a very disconcerting result to be achieved by the refinements of craniometry. On the other hand, it can scarcely have been on the anatomical features of the skull that Dr. Wunderly makes such a very definite statement, for the morphological characters referred to in the communication are quite insufficient for arriving at a dogmatic diagnosis of racial mixture between the Pleistocene ancestors of the present Australian and Tasmanian races. It might be considered among the triumphs of craniology to diagnose with certainty the product of racial mixture between the Australian and the Tasmanian of the historic period. It is a bold claim indeed to be able to recognize an isolated cranium of an individual as being the product of the racial mixture between the Pleistocene ancestors of these two races living (according to the geological report) more than 100,000 years ago.

It is probably the assertions of Wunderly and Adam that have led Mr. Mahony to include the sentence, "The Keilor skull, which combines Tasmanian with Australian characteristics, supports the theory that Tasmanians once occupied the Australian mainland", in his admirable survey of the whole question of the antiquity of man in Australia. From Australia it is postulated that the Tasmanians passed by way of the Bass Straits Islands into Tasmania. Perhaps, therefore, it would be well to point out that, altogether apart from the question of race mixture already mentioned, there are several other difficulties in the way of accepting this hypothesis. If Tasmanians and Australians had inhabited continental Australia side by side and had fused their races in Pleistocene times, it must be explained how it came about that the Tasmanian when first encountered by the white man had no dog, although the Australian had, even at the dawn of his story, dogs in plenty, for fossil dingo bones occur in Australia. No remains of the dingo, living or fossil, have ever been found in Tasmania or in the Bass Straits Islands; yet it is a historic fact that the Tasmanians eagerly seized on the cur dogs of the white man to assist them in their food quest. How came it that the Tasmanians remained ignorant of such familiar and important cultural developments as the use of the throwing stick, the stone-pointed spear, the boomerang and the shield, familiar enough and of widespread use in Australia ?

The National Museum and its director are to be congratulated on having placed on record the first really well-authenticated example of human remains, assignable to a definite geological horizon, that has so far been brought to light in Australia. Here we have a genuine human document of first-class importance. The skull is safe in the custody of the National Museum, and it is much to be hoped that all the other human fragments will be placed in its permanent collections. There will be many opportunities for further examinations of the skeletal remains by anthropologists, and meanwhile it would perhaps be better to accept them as permanent documents rather than to assume that the conclusions drawn from their first examination are necessarily the final ones.

COMPETITIVE RUBBER PLANTS*

By G. MARTIN

Superintendent of Research, London Advisory Committee for Rubber Research (Ceylon and Malaya)

FAR more plants contain rubber than is generally realized, but few contain enough to make extraction worth while. For example, the dandelion (*Taraxacum officinale*) is typical of the plants in Great Britain which, on bruising, yield a latex or milky fluid containing rubber; but the milk contains much more resin than rubber, and the latter only amounts to about 0·2 per cent of the plant.

The Russian dandelion, kok-saghyz, is similar in general appearance to English dandelions, but contains a much higher proportion of rubber, usually about 10 per cent. Experiments on the cultivation of kok-saghyz are being made in Great Britain, under the general direction of the Royal Botanic Gardens, Kew, as well as in other parts of the Empire and the United States, but it will be difficult, for the time being, to spare in Great Britain the tens of thousands of acres of good agricultural land which would be required to produce 1,000 tons of rubber a year, which is only 1 per cent of our imports prior to 1939.

The rubber-bearing plants of Great Britain are few and insignificant compared with those in other parts of the Empire. According to a report of the Imperial Agricultural Research Institute of India, there are in that country 268 species of plants which are stated to contain rubber. A list of rubber-bearing trees, bushes and plants in Africa, recently prepared by

* Substance of a paper read before the Royal Society of Arts on December 14.

the Imperial Institute, contained the names of 137 different species. Rubber-bearing plants also occur in Northern Australia, Ceylon and the West Indies. Although it would appear that the Empire is rich in rubber-yielding plants, most of them yield a complex mixture of vegetable substances of which rubber forms only a small percentage. No product containing less than 10 per cent is likely to be of value as a source of rubber, and even this proportion raises difficulties. This is unfortunate, as several plants yield copious supplies of latex, the solid content of which contains between 10 and 20 per cent rubber hydrocarbon. Probably the best known of these plants is the bush *Euphorbia tirucalli* and other species of Euphorbia in South Africa. One tapper can collect about two gallons of Euphorbia latex a day, which is equivalent to about 6 lb. of solids containing, at the most, 1 lb. of rubber. The most expensive item in the operating costs of rubber production is tapping and collection, and more than ten times the labour force is required to produce the same weight of rubber hydrocarbon from Euphorbia sp. as from plantations in the East. In addition, the rubber hydrocarbon of Euphorbia is mixed with six or seven times its weight of vegetable resins which make it soft and difficult to vulcanize without purification. The usual method of purification is to extract the resins with a solvent, such as alcohol. The purified rubber is of fair quality, and can be used in association with better rubber for many purposes. The mechanical difficulties of purification are, however, considerable and have not yet been overcome on a large scale.

In view of these difficulties it is probably easier and more economical in man-power and materials to find uses for the unpurified product in directions where the strength and elasticity of rubber are only required to a mild extent. This is the policy which has been pursued in Great Britain in connexion with the utilization of Niger paste, which is the coagulated latex of *Carpodinus hirsuta*, a vine widely distributed in West Africa. The paste contains little over 10 per cent rubber hydrocarbon, but intensive investigations by a number of organizations have indicated directions in which it can be used without purification, and which will save a corresponding proportion of good rubber for important purposes.

The rubber-bearing plants of importance in the present emergency yield products containing at least 75 per cent hydrocarbon, and some of them between 85 and 90 per cent, which is almost as pure as rubber produced on the Eastern plantations. Reference should be made, however, to a tree, *Ficus vogelii*, widely distributed in the forests of West Africa, which yields a product containing 50 per cent rubber hydrocarbon. Single trees furnish as much as 10 lb. of solids annually. The product is too impure for the more exacting uses of rubber, and, prior to the present emergency, there was no market for it. It can be used, however, in manufactures where a high proportion of rubber is not required.

The source which dominates all others is, of course, *Hevea brasiliensis*, which is a large tree about 60 ft. high, generally grown from seed, and is not ready for tapping until five years after planting. The trees are planted about 100 to the acre, and each mature tree yields about 5 lb. of rubber per annum. Some trees yield much more than this, and by grafting the buds of large yielders on to a suitable stock, it has been possible to develop progeny which yield more than 1,000 lb. per acre. The trees are tapped by removing a shaving of bark from a portion of the circumference. Immediately the cut is made, rubber milk or latex commences to exude and slowly flows over the cut surface into a cup attached to the tree. Each tapping yields about 3 oz. or more of latex, containing about 1 oz. of rubber. One tapper can tap about 300 trees per day, and so obtains about 15 lb. of rubber. The latex is transported to the estate factory, where the rubber is separated by adding an acid. The coagulum is then passed through mangles and finally dried either in air or in smoke.

The outstanding advantages of Hevea as a source of rubber are the large yield per acre, the low cost of collection, the low maintenance costs and the ease with which rubber of the best quality is separated from the latex. On the other hand, Hevea takes many years to reach maturity, and each individual tree then requires the attention of a tapper at intervals of a few days, and it is only because yields are high and labour is cheap that rubber can be produced at about 6*d*. per lb. After the latex has arrived at the factory and can then be handled on a large scale, the cost of manufacture is extremely small.

In the case of a small plant, such as kok-saghyz, it is possible to envisage a cheap annual crop based on mechanical cultivators, harvesters and mass-production factories. The retail price of beet sugar suggests that dandelion farms, supplying central factories, may be able to produce rubber at 6*d*. per lb. so long as yields are good and the technical side runs smoothly. Yields are not yet good enough in a strictly competitive market, and factory treatment requires further study.

The difficulties involved are illustrated by the fact that guayule, a product of the bush *Parthenium argentatum* which can be grown and treated like kok-saghyz, has struggled along for twenty years, receiving intense scientific and practical study in California and is still unable to compete with Hevea. Guayule rubber is, however, a much more resinous product than kok-saghyz and the bush is rather difficult to cultivate, so that the slow progress of guayule is not a satisfactory guide to the rate at which developments may be expected in kok-saghyz.

A considerable amount of attention is now being devoted to a woody climber, known as *Cryptostegia grandiflora*, which is a native of Madagascar, but grows like a weed in northern Australia, in various parts of India, in Florida and the West Indies. The Americans think so highly of this plant that they have recently arranged to plant 100,000 acres in Haiti. A large area has also been planted in India, and experiments are in progress in Australia. The chief advantage of this plant is that it grows about 6 ft. in the first year, forming a stem about 1 in. in diameter, which is then ready for tapping. It can be planted 10,000 to the acre, is not exacting with regard to climate or soil, continues to thrive when cut and produces an abundance of seeds which are very fertile. The rubber is not quite as good as that from Hevea, but contains about 75 per cent hydrocarbon and can be used satisfactorily for practically all purposes. The method of tapping most favoured at the moment is to tie together the ends of, say, 12 shoots, cut off about 1 in., and then immerse them in a small container. A few drops of latex fall from each shoot and there remains behind a small button of rubber on the cut surface, which is subsequently removed. Estimates of yield per acre vary between

200 and 750 lb. per annum, but estimates have a habit of not being reached in practice, and experience at present is very limited.

Other sources of rubber were intensively developed thirty years ago and have only faded into the background because of the economic predominance of Hevea. Some of them are large trees like Hevea, some are vines and others are shrubs. They all yield reasonable amounts of good-quality rubber and are being exploited to-day in so far as labour is available.

The most important of the trees is *Funtumia elastica*, which is widely distributed in the forests of west and east tropical Africa. Under forest conditions, it is a large tree with a straight trunk and smooth bark and does not branch until it reaches a considerable height. The usual method of tapping is to remove a small vertical channel of bark, the tapper, by means of ladders and slings, climbing to a height sometimes of 60 ft. As he descends he makes inclined incisions, joining the main channel, and so forming a herring-bone pattern on the tree. The latex exudes and flows along each of these side-channels and down the main channel into a small receptacle attached to the tree near its base.

When Hevea is tapped, the cut surface remains vital, and, on removing a fresh shaving a few days later, the latex again flows and the irritation of continuous tapping causes the flow of latex to increase. This is known as wound response. In the case of Funtumia, the lower edge of the cut dries up and suffers from die-back, so that in order to obtain more latex it is necessary to remove a very thick shaving of bark or to tap in an entirely different position. This eventually results in the death of the tree. Ingenious methods have been devised to overcome this difficulty, but they do not appear to be universally successful. Whatever method is employed, the first tapping yields the most latex, after which the yields rapidly decrease, even when an interval of several months elapses between each tapping. The amount of rubber obtained at the first tapping is usually about 4 oz., so that in order to obtain 10 lb. of rubber, which is the minimum daily output of a tapper in Malaya, it is necessary for one man to tap forty Funtumia trees. In view of the height to which these trees are tapped, and the fact that one acre of forest may contain only two or three trees, it is impossible for wild Funtumia rubber to compete with plantation Hevea.

In the early days of the rubber-growing industry, it was urged that since Funtumia trees were so widespread in Africa, it was the ideal tree to grow on plantations in that country. The argument had considerable appeal; but tapping difficulties and the poor yield, with consequently higher costs of collection, were fatal, and most of the plantations were eventually abandoned. Those which have not been destroyed are proving of value in the present emergency, but so far the problem of economic production remains unsolved, and there is no indication that after the War the exploitation of these trees will be continued. The rubber is of excellent quality, but not quite so good as Hevea rubber.

Another tree which attracted much attention in the early days is *Manihot glaziovii*, more popularly known as ceara. It is a smaller tree than Hevea and can be planted more densely. Whereas Hevea plantations usually have 100 trees or less per acre, ceara plantations have about 300. The tree is also less exacting with regard to climate and soil. This suggested to the early planters that the ceara tree might be grown in localities where the conditions were not favourable to Hevea, particularly in parts of Ceylon and in East Africa. The tree grows very quickly from seed, and can be tapped after two years. This is of great interest in the present emergency, in which the development of quick sources of rubber is of strategic importance. It is only fair to point out, however, that no authoritative information is available about the yields of young ceara or about the quality of the rubber. The tapping of young trees with thin bark, small surface and poor yields presents considerable difficulty and has not been studied as a commercial proposition.

Even the mature ceara tree is not easy to tap, and the yields are so low in the dry areas that insufficient latex exudes to overflow into a receptacle. A higher yield is obtained in the more humid areas, but an annual yield of 200 lb. per acre, containing 300 trees, is above the average and compares unfavourably with Hevea. Very high yields are recorded for individual ceara trees—as much as 10 lb. per annum. This corresponds to 3,000 lb. per acre, if it is possible to develop reliable, high-yielding offspring, but the low yield is not the only factor operating against future development. The ceara tree does not stand up well to tapping, particularly in the dry areas. So late as 1914 it was reported from Ceylon that no method of tapping the tree was known which did not cause death. In addition, the bark of the ceara tree has a hard outside layer, which quickly blunts the tapping knives, and which also tends to separate from the inside layer which contains the rubber-bearing vessels. It is usual, therefore, first to remove the outside layer from the area which has to be tapped, and then to employ a conservative system of tapping so as not to injure the tree.

There are a number of abandoned ceara plantations, particularly in East Africa, which have now been reopened, but prospects after the War do not appear promising.

The most important indigenous sources of rubber in Africa are the numerous woody large vines, widely distributed in the tropical forests. The principal genera are Landolphia, Clitandra and Carpodinus, containing numerous species. The best sources of rubber are confined to four or five species of Landolphia in West Africa and a similar number in East Africa, together with a little Clitandra and Carpodinus. The vine rubber from these sources is of excellent quality, that from the Landolphia spp. containing about 90 per cent hydrocarbon in West Africa and 85 per cent in East Africa.

In the rubber boom of 1910, when the total output from all sources in Africa reached 20,000 tons, vines were recklessly tapped and, in many cases, completely destroyed. A vine requires about ten years to grow from seed and about five years to grow again when partially cut down, so that the damage done during the rubber boom is by now largely repaired; but the balancing of productive capacity against probable useful life is still important, particularly as there is a risk of obtaining much rubber at first and none during the rest of the war period.

A usual method of tapping is to cut the bark at intervals, and climbing among its twisted branches for the purpose is regarded as hard and dangerous work. The yield is 1–8 oz. of rubber per vine, and

after several months, when the cuts have healed, the treatment can be repeated. An area of forest containing two vines per acre is regarded as a rich source of rubber, so that 1 lb. of rubber per acre is an excellent yield. A cautious tapping treatment would probably have little effect on the life of the vine; but the tendency is to get as much rubber as possible with the least effort, so that it will not be surprising if the yield of vine rubber reaches a peak and then diminishes as the sources of supply are destroyed.

In normal circumstances vine rubber cannot hope to compete with plantation rubber produced in the Far East, chiefly because the harvesting of the rubber involves the same type of operations with much smaller yields and more difficult conditions. This comment does not apply, however, to some species of Landolphia, etc., particularly *Landolphia thollonii*, which, growing in poor soil in open country, does not develop into a climbing plant, but throws out long underground stems ramifying in all directions, with small tufts of foliage above ground at irregular intervals. The bark of these stems contains about 15 per cent rubber and in some areas, particularly in French Equatorial Africa, there is such a mat of stems that every footstep covers a treasure of buried rubber. The stems have been known to reach sixty yards in length, and as they are only a few inches below the surface they are not difficult to gather and cut off near the tap root. They are then dried a little to coagulate the latex, cut into convenient lengths and smashed with a mallet so as to facilitate the removal of bark. Finally comes the laborious operation of pounding the bark, so as to convert it into a powder and mass the rubber together into small lumps. It is estimated that 15 hours beating is required to produce 1 lb. of rubber. Since the supply of labour is limited, such a process cries out for mechanization. One method is to run the bark for some time through heavy grooved mangles, that is, ordinary rubber washing machines; but these machines are difficult to obtain under present conditions, and there is only a small output for a given input. A study of the problem in Great Britain and in South Africa suggests that the most suitable type of grinding machine is a rod mill, consisting of a revolving cylinder containing loose rods which rise and fall and rotate as the cylinder revolves. The mechanical method is essential to the success of several of the new sources of rubber, such as the Russian dandelion, root rubber, the bark of vine rubber from which the latex does not flow freely and even for bark shavings obtained on plantations in Ceylon, which were often thrown away because they contained only 5 per cent rubber. On a large scale it should be a fairly cheap method of obtaining rubber, particularly if a continuous process can be devised.

A survey of competitive rubber plants would not be complete without a reference to Castilloa and *Ficus elastica*. Both have been cultivated on a small scale in different parts of the Empire, but on account of small yields, and for other reasons, cannot hope to compete with Hevea after the War. The whole trend of this paper shows that trees which have to go through the same cycle of operations as Hevea in order to obtain rubber are hopelessly outclassed by the latter with regard to yield, quality and ease of treatment. Small plants may be more successful, however, because their cultivation and treatment can be mechanized, and operations can be based on an annual instead of a daily cycle.

OBITUARIES

Prof. W. W. C. Topley, F.R.S.

WILLIAM WHITEMAN CARLTON TOPLEY was born in 1887. He was educated at the City of London School, St. John's College, Cambridge, where he obtained a first class in the Natural Sciences Tripos, and St. Thomas's Hospital, London, and qualified in medicine in 1909. In 1910 he was appointed director of the Pathological Department at Charing Cross Hospital, and started a private practice in Harley Street.

In 1914 he accompanied Colonel Hunter to Serbia, where an epidemic of typhus was raging. There is little doubt that his sensitive nature was stirred by the tragedies he saw in a community affected by infectious disease, and that this experience decided his main line of research, namely, an experimental study of the factors involved in the spread of epidemic disease. He returned to England in 1916 and rearranged his life so that he could devote himself entirely to research and teaching. He quickly set to work and showed from the very outset how hard and fast he could work, a characteristic which has staggered all those who have followed his activities.

In 1919 Topley's researches were attracting much attention, and he made a preliminary report of them in the Goulstonian Lectures. In 1922 he accepted the chair of bacteriology at Manchester, and for five years rigidly limited his interests; with a small group working devotedly around him he studied the spread of epidemic disease in mice.

In 1927 he became professor of bacteriology and epidemiology at the London School of Hygiene. Here, in association with Greenwood and other colleagues, he carried on his researches, the results of which and the views which emanated from them he wrote up in his clear, forceful and interesting style. He delivered the Milroy and Harben Lectures, and in 1930 the importance of his work was recognized by his election to the Royal Society. In addition, he threw great energy into the academic diploma course of bacteriology which he had started, and wrote with G. S. Wilson a large text-book of bacteriology. He began, moreover, to take an interest in committee work, and allowed his scientific interests to develop more widely by seeking contacts with scientific men working in other branches of biological research.

In a very short time Topley was serving on the Council of the Royal College of Physicians, the Council of the Royal Society, the Medical Research Council, and the Animal Diseases Committee of the Agricultural Research Council. His book had been an outstanding success; and scientific workers from every side were asking for his time, help and advice. He responded to these added burdens by increasing the tempo of his work and thought, by working harder, and by arranging and rearranging his mode of life so as to attain maximum efficiency.

In 1939, certain that war was coming, Topley was determined to prevent, if possible, the tragedy of infectious disease spreading through the community. Largely due to his efforts, the Emergency Public Health Laboratory Service was set up in Great Britain to combat this danger. At the same time he gave his help to a group of pathologists who, as a result of the experiences of air-raiding in the Spanish War, were pressing for an effective blood transfusion service for the London area, and the London Emergency Blood Supply Depots came into being. As

the Medical Research Council was administering both these services on behalf of the Ministry of Health, he worked during 1939–41 at the Council's head office, developing both services and engaging himself in a host of other war problems with which the Council was concerned. In addition, he was available to all and every scientific worker who, in the stress of war, questioned whether his services were properly employed, or required moral support for carrying on. Even in the midst of all this work, he gave the Croonian Lecture before the Royal Society in 1941, entitled "The Biology of Epidemics". Those who heard him may have felt that this was the swan song of his research experience, but none thought that it was the last time they would hear him, in public, develop a story in his clear, logical and arresting manner.

In 1941 the Agricultural Research Council asked Topley to become its secretary. Few would have considered such a change or such an exacting post unless prepared to sever their old scientific life completely, but Topley could never view it in this light. He believed that if he but drove himself harder, he could master his new duties and keep his old interests and friendships alive. How well he mastered his new work in the two years allotted to him it is not yet possible to judge, but it is clear that revolutionary changes in veterinary research were impending. How anxious he was not to lose his old interests is shown by the very active interest he took in the part that he considered the University of Cambridge should play in the medical, veterinary and bacteriological sciences.

As a man in science, Topley was outstanding. The mainspring of all his activity was devotion to science. Disregarding, save for a caustic remark, those whose scientific integrity was in doubt, he gave without stint his sympathy, understanding and help to all other workers. No matter what it cost him, nothing was too much trouble if his help would increase a worker's efficiency and devotion. He was probably happiest when the young men of science sought his aid, for he knew that the future of science was in their hands and that the young were slightly scared of him. He did not understand why, and nor did they, when after a short time they always spoke of him as "Bill". A talk with him was not easily forgotten, for the ideas bubbled out of his bold and original mind, and he left a sense of exhilaration and enthusiasm which lessened difficulties and made the goal so much more worth the effort. He had that rare quality of brain which, though severely critical, was essentially constructive. He stimulated the hesitant, and spurred on the keen. His honesty of purpose and loyalty continually drew new friends to him, and he excelled in bringing groups of workers together. Frequently responsible for the inception and planning of a research, and for the guidance of the worker throughout, his generous nature allowed no recognition of the fact in the published work.

No one would have used so profitably (or enjoyed more) the period of reconstruction after the War, to further his wide scientific interests and the welfare of scientific workers and their technical assistants. This has been denied him, but his influence lives in so many that much that he desired must come to pass.

As a man, Topley was at times delightfully simple, and at others curiously complex. He had a strong sense of loyalty; nothing gave him more pleasure than his election to an honorary fellowship of his old College, and no man was more staunch to his friends. Yet he feared such loyalties lest they should hinder his service to science. He enjoyed recognition and praise for his election to the Royal Society, and the award of the Royal Medal of the Royal Society delighted him, yet he shunned these delights lest an undue taste for them should chance to warp his judgment. Severely critical as he was of others, he was much more critical of himself. No one was less in need of self-criticism, but this may have been responsible for the curious complexity which he sometimes exhibited.

Those of us who visited him in his home believe we hold the happiest memories. Topley was still the wise man of science, arguing and discussing; but he allowed more latitude to his exuberance, to his puckishness of mind, and he fitted so well into the delightful home background which his wife so unselfishly created for him.

Topley died suddenly at work in his office chair on January 21. Thus passed away, in a manner which he himself would have chosen, an outstanding man of his generation. A. N. DRURY.

Sir Aurel Stein, K.C.I.E., F.B.A.

SELDOM can there have been an instance of a task pursued so constantly, so indefatigably and with such zest through so long a life as by Sir Aurel Stein, who died on October 26, aged eighty. Oriental research, he acknowledged, had claimed him from his student days. More than that, the campaigns of Alexander the Great had fascinated him from first to last, so that he found a special satisfaction in following in his tracks, and, in some of his latest writings published since the beginning of the War in the *Geographical Journal*, turned again to the unravelling of his campaigns.

This pursuit of Oriental research and this fascination felt for the most dramatic incident in the intercourse of East with West, personal though they were, corresponded to a general urge in a period which has probably reached its close, so that, while from one point of view it is possible to regard his career as the fruit of his early self-preparation by work in the study and of persistent concentration on his aims, from another it was one of the main fruits of the impetus given to archæological studies by the viceroyalty of Lord Curzon and the reform of the Archæological Survey of India under Sir John Marshall. Though Stein was born in Budapest and educated in Vienna and Germany before first coming to England, his field-work was made possible by the Government of India.

It was under the Punjab Education Department that Stein first entered Indian Government Service, and while at Lahore he gave his spare time to the translation from the Sanskrit of Kalhana's "Chronicle of Kashmir" (Rājatār angīnī). Meanwhile, the vast regions of Central Asia were attracting explorers from many lands. The journey that claimed most attention at the time was that of the Swede, Sven Hedin, during the years 1893–97. This was undertaken mainly as geographical exploration, but he also carried out some archæological investigations in eastern Turkestan and on the Keriya River east of Khotan. It was, however, the linguistic interest of some birch-bark manuscripts brought back from Khotan in 1893 by Dutreuil de Rhins, to which Bühler directed Stein's attention, that led Stein in 1897 to plan his first journey to Central Asia. He found that antiquities were being brought in to Sir

George Macartney, then Consul-General at Kashgar, for transmission to Calcutta at the instance of Hoernle, who greatly encouraged Stein in his design of investigating their source. It was therefore from the first an archæological rather than a geographical exploration on which Stein started. His first expedition to Central Asia was delayed until 1900, when he set out via Gilgit and Kashgar for a year in the region of the Taklamakan Desert.

It is impossible even to sketch here the course or routes of Stein's three Central Asian journeys. They have been fully reported from several points of view by Stein himself, in narrative volumes, in full-length reports and also in two excellent and compendious sketches, a paper given before the Royal Geographical Society with the title "Innermost Asia: its Geography as a Factor in History", and published in the *Geographical Journal* of May and June 1925, and the section on his own archæological work in Central Asia which he contributed to an account of the work of the Archæological Survey of India published by the India Society in 1939 under the title "Revealing India's Past". Here we can only attempt a general estimate of his method and its fruits. His research was historical and directed especially to the solution of one historical problem—the elucidation of the relations between China and the West, the capacity of the trade routes, the nature of the cultural influences passing along them, the periods which saw these routes most used and the causes which led to the abandonment of them and of the settlements along their course. A striking fact is that whereas he started out with the idea above all of tracing the eastward expansion of the cultural influences of the Hellenistic West, and of India, he came more and more to be impressed by the purpose, organizing power and tenacity of the Chinese who opened these routes and so long maintained them. Hellenistic influence was found to end in the early years of the fourth century A.D., but Indian influence was long continued by the passage of Chinese pilgrims to the Buddhist shrines in India. For the early period his most important discovery was of the elaborate organization of a Chinese *limes* in the Han period, protecting the route through the Tunhuang Oasis and beyond from the incursions of the nomads of the steppe to the north; and of the route, across the bed of the dried-up inland Sea of Lop, connecting this region with Kucha without passing through the relatively exposed Turfan region.

For the history of art Stein's most important finds were the textiles of the Astāna cemetery and the cache of paintings and manuscripts in the walled-up chamber at the Caves of the Thousand Buddhas, near Tun-huang. These with the wall paintings, transported from the sites of Bazaklik, Murtuk, Miran and elsewhere to the new Central Asian Antiquities Museum at New Delhi, have added so much to the material for the study of Buddhist painting in China in the T'ang period as to revolutionize it. Unfortunately, the wall paintings, though listed by Dr. Andrews in his Catalogue of 1933, have not yet been published, and are therefore not yet fully available to students. The Tun-huang paintings, on the other hand, have been fully catalogued by Mr. Arthur Waley, and the whole series was mounted at the British Museum and a great part exhibited there in 1914 on the occasion of the opening of the King Edward Building. The collection was afterwards divided between the British Museum and the Government of India for the Museum at New Delhi, but in 1921 the two Museums brought out jointly a portfolio of reproductions in colour of selected examples from both collections, with an introduction by Laurence Binyon and descriptions by Stein himself. Their importance has therefore been fully realized, though much work remains to be done on them from the stylistic and iconographical sides.

Stein went no more to Central Asia, except for a brief and abortive journey. But, though prevented from following up one line of research, he started on the archæological survey of another great region. He had already traversed Sistan on his return from the third Central Asian expedition, and he now began a series of journeys which eventually covered the whole of that great bridge between the civilizations of East and West which leads from Mesopotamia, over the Iranian plateau, through Afghanistan, and so down into the Indus Valley; or across the Oxus into Turkestan. During all this period of more than twenty years he had two bases, his camp in the Kashmir highlands, and Corpus Christi College at Oxford, where the late president, Dr. P. S. Allen, the Erasmus scholar, always welcomed his friend on his visits to England. Of these journeys, the most important were the tours of the chalcolithic sites of Baluchistan in 1926–27 and 1927–28, and, since 1930, in south-western Persia. His accounts of the first were published by the Archæological Survey of India in its series of Memoirs; the later journies undertaken after his retirement from its service were chronicled in two large volumes. He also made expeditions to the Upper Indus region and followed the Roman frontier *limes* in Mesopotamia.

In all this wide area, Stein followed the course of ancient trade routes with his trained eye and indefatigable zeal. His pertinacity and complete absence of fear carried him over the wildest and most forbidding country. Indeed he was most truly himself when, with his surveying staff and train of porters alone, he viewed from some almost inaccessible spot ancient tracks and, as it were, a whole panorama of past history. Where written texts could illumine the records which he found on the ground, all the evidence which he found fell into a pattern. But in a region of such a long and complex history as he was now exploring, it was not to be expected that Stein should have been able to reach conclusions as definitive as in Central Asia. His explorations have mapped the sites which need to be studied: they call for the methods of the trained excavator and much comparative study before they can yield all their evidence.

Aurel Stein loved solitude. He was happy in a study, but happier in the wide open spaces. When he appeared in the lecture room, as he did in the United States at the Fogg Museum and elsewhere, and in London especially in the Royal Geographical Society's rooms, it was the nervous force of his small compact body and his piercing eye which impressed one with his indomitable spirit even more than the substance of what was said. At over eighty he was hoping to embark on a fresh field of exploration from Kabul, where death claimed him. It was his wish that his body should rest amid the beautiful scenery of Kashmir.

BASIL GRAY.

Dr. M. Radford

THE passing of Dr. Maitland Radford, medical officer of health of St. Pancras, at the age of fifty-nine, is of more than local or professional significance. He was a rationalist, reared in a progressive if not

revolutionary atmosphere, with Shaw, Wells, William Morris and Bradlaugh as friends of his family. He was a nephew of Graham Wallas, whose influence he always gratefully acknowledged. Educated at Abbotsholme and University College Hospital, his career in public health was that of a successful and efficient sanitarian. But, as a close colleague of his has written, "he was not a man to allow the local trees to obscure his vision of the public health wood, or as he might have said, the public health jungle".

Widely and deeply read in literature, philosophy and economics, it was perhaps in health education in its widest sense that he found great satisfaction. The Central Council for Health Education, of which he was vice-chairman, owes much to him. But it was not the leaflet or the poster or the film which interested him most. It was rather the plan, the purpose of it all, the thought of the human personality rather than its physical frame.

He was a man of principles and ideas, preferring the long to the short view. Modest and urbane in manner, he was frank in the confession of his doubts, and both adamant and passionate in defence of principle. He was one of the few men of whom it can truthfully be said that nothing would induce him to say and do anything which he did not believe to be right. His defence of the secular approach to moral problems at a recent conference on venereal disease, at which the Archbishop of Canterbury was the principal speaker, will long be remembered by those who heard it.

In conference or conversation—he preferred conversation—the ideas simply tumbled out, or to be more accurate, shot out. Some he pursued himself, others he left his colleagues to pursue. Strange though the country through which they led the pursuer, they were worth pursuing. He prodded the conventional—but oh, so gently. He flicked the obstinate with a wit as innocent as it was penetrating. He 'rollicked' the reactionary with a mirth that was infectious. He was, above all, a thinker; and with the world as it is, that marked him out and adds to our sense of loss.

C. Hill.

We regret to announce the following deaths:

Dr. Carl Bonhoeffer, successively professor of neurology at Königsberg, Breslau and Berlin and one of the editors of the *Monatschrift für Psychiatrie*, *Allgemeine Zeitschrift für Psychiatrie* and *Zentralblatt für Neurologie und Psychiatrie*, aged seventy-five.

Mr. Christopher Dalley, president of the Institute of Petroleum, an authority on petroleum engineering, on January 27, aged sixty.

Dr. A. Stansfield, emeritus professor of metallurgy, McGill University, on February 5, aged seventy-two.

NEWS and VIEWS

Scientific Terminology

The enormous waste of human time and energy, nay also of human life, that has been caused by the use of wrong or vague words, and the misuse of good words, is well known to students of human thought through the ages. Many words have changed their meanings in the course of time, and new words have been adopted with ambiguous or multiple connotations. Though one would hesitate to suggest that the legal profession has been the chief perpetrator of such intellectual delinquencies, and of their *sequelæ*—for the theologians and philosophers must have run them very close—there is no doubt that the loose drafting of governmental Bills and Regulations, even up to the present day, has caused great confusion and, incidentally, served to redistribute wealth in a unilateral direction. As Mephistopheles remarked, "Mit Worten lässt sich trefflich streiten, Mit Worten ein System bereiten, Von einem Wort kein Iota rauben".

To-day most new words originate in the sciences or their applications, and many of them have been condemned or criticized owing to their lack of precision, their hybrid etymology, their ugliness or unwieldiness, or because they signify something different from identical or similar words used in common parlance. It has often been deplored that in Britain we have no institution or high authority to adjudicate on new words, like the French Academy does for France, albeit often with much delay; but there seems to be no reason why the scientific world should not take the bit between its teeth and appoint its own authority for rectifying bad words, including spelling, devising new words or deciding between rival suggestions. An 'omnibus' body, like the Royal Society, is clearly indicated to assume such a task. Through *ad hoc* subcommittees for groups of sciences, assisted by a few language experts, it could provide authoritative guidance, if not compulsory ruling, for scientific research workers, who are seldom as good at word-building as they are at 'things'. The main committee might also attack the problem of an international auxiliary language for use in science and technology.

Photographic Terminology

The above reflexions arise from a perusal of a letter addressed to the scientific Press by the editor of *Photographic Abstracts*, entitled "Microphotography and Photomicrography, and other Terminological Inexactitudes". Although these two terms, signifying the production of very small photographs and the photographic reproduction of very small objects, respectively, are clear enough to experts, they are confusing to other people, and one can support the author's plea for the standardization of these and similar terms. 'Micro-' and 'macro-', he suggests, should be used in photography with a definite quantitative meaning only, and one might go farther and suggest that when these prefixes are used for scientific words, they should bear a precise quantitative meaning, as in microgram and microhm, leaving their vaguer signification to popular words like microcosm, macrocosm and perhaps 'microcookery' (the cooking of war-time rations). The word 'radiogram' is one that needs immediate attention, as it has three distinct meanings: (1) a combination of radio-receiver and gramophone, (2) a telegram transmitted by radio, and (3) an X-ray photograph (also called a radiograph or a skiagraph). Probably (3) would be best for scientific use. The word 'radio' itself might be banned from scientific writing, for, at least etymologically, it might refer to any kind of radiation. But such difficulties as these are not to be solved offhand; they would best be considered by an authoritative body, as suggested above.

Water Resources of Great Britain

MR. H. U. WILLINK, Minister of Health, in a statement in the House of Commons on February 10, said that the Government proposes as part of its general reconstruction programme to introduce legislation making possible further Exchequer assistance for the extension of piped water supplies in rural localities. This will apply also to sewerage in such areas. A White Paper is in preparation outlining the Government's general proposals with regard to water; these will include provision for an adequate scientific assessment of resources and for the control and co-ordination of their use and distribution. It is hoped to issue the White Paper about the same time as the introduction of the Bill. It will deal with schemes on national lines.

Standardization of Non-Ionizing Radiations

THE Medical Research Council has appointed the following committee to advise and assist in promoting the quantitative study of the non-ionizing radiations, particularly in relation to their medical applications: Prof. H. Hartridge (chairman), Mr. P. Bauwens, Dr. R. B. Bourdillon, Mr. E. Rock Carling, Prof. J. A. Carroll, Mr. J. Guild (nominated by the Department of Scientific and Industrial Research), Prof. F. L. Hopwood and Prof. W. V. Mayneord (secretary). In 1928 and 1937 satisfactory units for the measurement of ionizing radiations were agreed internationally, and there is urgent need of a corresponding standardization for the non-ionizing radiations. Under this heading will be included infra-red, visible and short-wave wireless radiations, but it may be found advisable to deal also with ultra-violet and ultrasonic radiations, since none of these was covered by the earlier recommendations.

Transmission and Distribution of Electricity in Mines

A PAPER on this subject was read before the Institution of Electrical Engineers in London on February 9 by B. L. Metcalf. In the South Wales coalfield, where approximately 16 per cent of the total output of Great Britain is raised, the transmission and distribution of electricity introduces special problems owing to the hilly nature of the country. To give some idea of the potential demand at collieries to be obtained, the load for a typical group of collieries is analysed. Some notes are included on the choice of switchgear for collieries and on the influence on this choice of the proposed amendments to the Regulations for the Use of Electricity in Mines. Information is given regarding the damage to transmission towers during the ice storm of 1940, and a proposal is made to amend the regulations of the Electricity Commissioners governing ice-loading for conductors. A new design of cross-arm for a single-circuit 33-kV. overhead line is illustrated. Recommendations are made for the standardization of equipment required for the electrification of collieries.

The magnitude of the potential colliery electrical load should be given full consideration in any plan for the generation, transmission and distribution of electricity in any industrial mining area. Electrification of the collieries in any area would be simplified and cheapened by greater standardization of the sizes of units adopted. Standardization could be applied with advantage to switchgear, transformers, compressors, haulages, winder drums, transmission-line cross-arms, cable sizes, voltages, etc. The subject of pit-head generation is touched on only as it affects the general problems of transmission and distribution, but it is one which demands full and thorough technical investigation in all its aspects, and in relation to the location of washeries, existing generating stations and transmission lines, coal freights and other local industrial loads.

Man's Influence on Seismic Movements

WALTER KNOCHE has an article with the title "La Accion Humana Como Una Causa Posible De Liberar Movimientos Sismicos" in *Anales de la Sociedad Cientifica Argentina* (135, Ent. IV and V, 1–41; 1943) which suggests a number of ways in which the progress of civilization can influence earth movements. A few of these will be referred to in the following brief summary. The weight of matter transported by the great rivers and deposited at their mouths depends on the denudation which takes place, and this, in turn, depends on the nature of the soil, the presence of vegetation, and other factors which are under the control of man. Variations in isostasy in the deltas of rivers as well as in the regions of denudation are, therefore, indirectly due to human agency. Then again it is pointed out that oscillations in the earth's axis might be produced by the displacements of matter through fluvial transportation, and this latter depends on man's interference with the vegetation. Another important factor is fires which destroy vegetation and so release a considerable weight over certain parts of the earth's crust. The loss of weight on land appears as an increase in the oceans, which receive a great portion of the burnt vegetation in the form of carbon and water. The weight of great cities with their inhabitants, such as San Francisco and Tokyo, is able to originate earth movements, more especially in those regions of the earth where there is a certain amount of instability. It seems possible to conduct research on the influence of re-afforestation in mitigating the danger of denudation and devastation on the earth's surface, and in this way to estimate the extent of the human factor in the production of earth disturbances.

The Dominion Observatory, Wellington

THE report for the year ended December 31, 1942, of the Dominion Observatory, Wellington (Bull. No. *R*28) deals chiefly with time service and seismology. During most of the year the control of the time service was greatly facilitated, enabling additional check time signals to be received from Greenwich and Washington. The clocks were seriously affected by local earthquakes on June 24, August 2 and December 2, but they suffered no permanent damage. The free pendulum was frequently disturbed by local earthquakes, and investigations showed that marked changes of rate are not due to defects in the clock mechanism but are associated with one or other of the following causes: (1) violent fluctuations in barometric pressure; (2) changes in the direction of local ground tilt; (3) local earthquakes. The severe outbreak of seismic activity in the Wairarapa district on June 24, 1942, followed by severe aftershocks on August 2 and December 2, has been already referred to, and a considerable number of subsidiary shocks also occurred, six hundred being recorded at Wellington. On June 27 a shock took place the epicentre of which was near White Island. The focal depth, 230 miles, was the deepest origin so far recorded in

the New Zealand region. Another notable occurrence was a shock on November 1, centred in the south-east Tasman Sea, about 150 miles off the Milford Sound coast. Information is given in the bulletin on various other matters connected with the different seismographic stations and their instruments, on the research carried out on the distribution of earthquake activity in New Zealand, and on matters of general interest.

War and Rheumatic Fever

According to an article in the September issue of the *Statistical Bulletin* of New York, war conditions generally favour an increase of rheumatic fever in the armed forces. This was seen not only in the War of 1914–18 but also in the present conflict, in which many cases have been reported among the younger men enlisted. Susceptible individuals are usually attacked shortly after reporting for duty. About 40 per cent give a history of infection in childhood; but in a significant proportion there is no history of a previous attack. The seasonal distribution of the cases is typical, the peak being reached in the late winter and early spring. In the great majority of cases there is a history of upper respiratory infection or of scarlet fever. In the general population, however, both in the United States and in England, there has been a decline in rheumatic fever and rheumatic heart disease during a war period, the decline being attributed to decreased amount of poverty as a result of full employment, the better feeding of children, especially the increased provision of milk, and the evacuation of children from metropolitan areas.

Names of Biological Colours

Prefaced by a brief discussion, H. A. Dade (Mycological Papers No. 6: Colour Terminology in Biology. Pp. 25. Kew: Imperial Mycological Institute, 1943. 3*s*. 9*d*. net) has provided a useful dictionary list of the names of colours, cross-referenced as to synonyms, that are or may be employed, particularly as trivial names, in biology. Appended to this is a list of the words indicative of tone or texture, and two charts which give the position of the names in relation to Ridgway's "Chromatic Scale". This should prove very useful to systematic biologists, in particular those without adequate knowledge of the Classical languages, for quite frequently trivial names supposed to be indicative of colour are incorrectly applied, and sometimes so badly that they are misleading. It is to be hoped that now such an aid is available this will not occur so often in the future.

Equilibrium Diagrams of Binary Alloy Systems

"The Equilibrium Diagram of the System Aluminium-Zinc" is the title of the first of a new series of publications which the Institute of Metals proposes to issue of up-to-date equilibrium diagrams of binary alloy systems. Each of the series will consist of the diagram reproduced on a large scale and based on the most reliable work in each phase-field, a table providing all the important data connected with this diagram, critical notes and a list of references. This initial publication, the work of G. V. Raynor, appears to satisfy all these points in an excellent manner, and whets one's appetite for the three others so far promised, on the copper-tin, copper-zinc and copper-aluminium alloys respectively. It is available from the Institute at 4 Grosvenor Gardens, S.W.1 (6*d*. post paid).

Thoughts on Reconstruction

The April, June and September 1943 issues of the *Krisson Bulletin* contain a series of articles well designed to encourage the development of a more scientific outlook generally. The first, "A Plea for Scepticism", should encourage a more critical attitude to some of the proposals for reconstruction and particularly to political theory. It includes a useful little bibliography. In the following issue are printed eleven paragraphs of "The Universal Rights of Man" from a pamphlet by Mr. H. G. Wells to be published later. This is a development from the "Declaration of the Rights of Man". This statement of the universal rights—the right to live, protection of minors, freedom to work, right to earn money, right to possess, freedom to go about, right to know, personal liberty, freedom from violence—which are in the nature of man and cannot be changed, but could be made the basis of a new and happier way of human life, is accompanied by an appeal not to take them for granted but to work for them and to guard them. The third article, "Educated? It *is* my Business", after quoting F. Sherwood Taylor's "The Century of Science", pleads for an attempt to understand our environment and to take an intelligent place in human organization.

Announcements

Dr. E. F. Armstrong has been appointed chairman of a commission appointed by the Conference of Allied Ministers of Education to report on the problems involved in the supply of scientific equipment to the occupied countries when they have been freed.

The Council of the Institution of Naval Architects has awarded the premium of the Institution for the year 1943 to Dr. J. F. C. Conn, for his paper "Marine Propeller Blade Deflection".

A research scholarship of the value of £400 a year and tenable for two years has been offered by the Wrought Light Alloys Development Association to encourage and facilitate research in the application of light alloys to ship construction. The scholarship will be administered by a committee of the Institution of Naval Architects and it is hoped to make the award in September. Full particulars of entry, which closes on July 31, can be obtained from the Secretary, Institution of Naval Architects, 10 Upper Belgrave Street, London, S.W.1.

The Chancellor of the Exchequer has stated in a written Parliamentary reply that the Government, after considering a report from the University Grants Committee, has decided to maintain the provision for universities and colleges in the Estimates for 1944 at its existing level.

The Council of the American Astronomical Society has awarded the Annie J. Cannon Prize for women astronomers to Miss Antonia C. Maury of Hastings, N.Y., for her distinguished work at the Harvard College Observatory in the early days of spectral classification. Miss Maury at the turn of the century devised her own system of classifying the spectra of the stars on the basis of detailed descriptions of their characteristics as obtained from high-dispersion spectra. These details have since been shown to have great significance in revealing the physical characteristics of the stars.

β-Radiation from Active Phosphorus and Sodium

IN order to investigate the β-radiation from active phosphorus, phosphorus pentoxide was irradiated with 5 MeV. deutrons (current approximately 40 μ A.) in the cyclotron of this Institute. A very small fraction of the sample (about 0·01 mC.) in the form of $Mg_2P_2O_7$ was placed between two foils of about 0·02 μ thickness, the preparation forming a narrow strip 7 mm. × 0·5 mm. It was then introduced into a β-spectrograph of the lens type[1] with high intensity and good resolution (in this case 1·9 per cent), and provided with a very thin foil (0·2 μ) in front of the Geiger-Müller counter. To obtain the true distribution curve, the number of particles counted must be divided by the corresponding value of $H\rho$. The spectrograph was calibrated by using the I line of thorium B, the energy of which had been determined as $H\rho = 1750$ in the semicircular spectrograph of the Institute.

If we plot $\left(\frac{N}{f}\right)^{1/2}$ against $\sqrt{1+\eta^2}$ $\left[\text{where } f(z,\eta) = \eta^2 \cdot \frac{2\pi y}{1-e^{-2\pi y}};\ y = z \cdot \frac{\sqrt{1+\eta^2}}{137\eta};\ \eta = \frac{H\rho}{1700}\right]$ we should, according to Fermi's formula of β spectra, obtain a straight line. The Fermi diagram obtained is seen in Fig. 1. Evidently the curves are quite straight except at lower energies. For energies where $\sqrt{1+\eta^2}$ is less than 2, the experimental curves give more particles than are predicted by the Fermi formula. It is possible that this can be explained by the occurrence of scattering in the backing foil or more probably in the source itself, a process which should undoubtedly give rise to low-energy electrons. In view, however, of the thinness of the foils and narrowness of the source, this can scarcely account for the very pronounced excess of low-energy electrons in comparison with the theoretical number. According to our conceptions of the β-emission by phosphorus, this constitutes a so-called 'forbidden transition'. The Fermi formula is rather developed on the assumption of a permitted transition and, according to Fig. 1, probably cannot explain the energy distribution in this case.

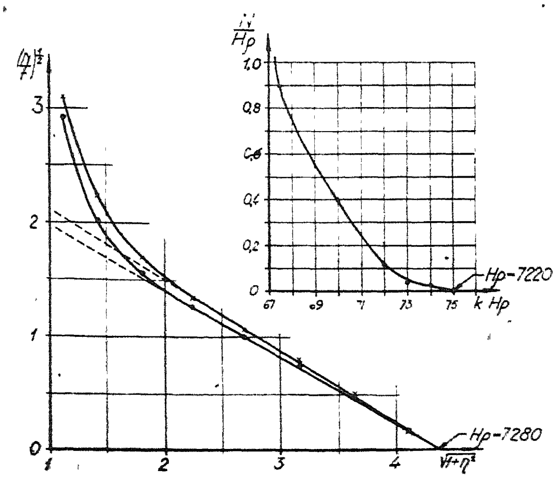

FIG. 1.

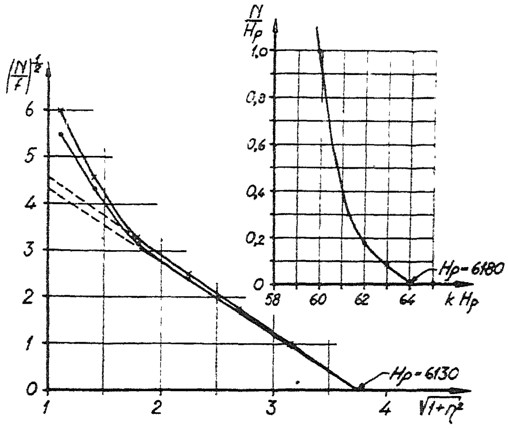

FIG 2.

The straight part of the Fermi curve cuts the axis at $H\rho = 7280$, which fits well with the direct determination of the upper limit (corrected for the finite power of resolution) $H\rho = 7220$ or $1{\cdot}71 \pm 0{\cdot}02$ MeV., which is marked in Fig. 1. The value for the upper limit seems to be in good agreement with determinations by Lawson[2] ($H\rho = 7210$) and Lyman[3] ($H\rho = 7150$) made by the semicircular method.

With sodium, ^{24}Na, a β-radiation is emitted which also corresponds to a forbidden transition. To study this radiation, sodium hydroxide was irradiated in the cyclotron for some hours and a very small fraction of the sample in the form of sodium chloride was treated as before and introduced into the β-spectrograph. After correction for the falling off of the intensity due to the disintegration ($T = 14{\cdot}8$ h.) the two Fermi curves in Fig. 2 were obtained, where the upper limit is also marked. Apparently the Fermi curve is similar in shape to that for phosphorus, with more low-energy electrons than might be expected from the theory of permitted transitions. When $\sqrt{1+\eta^2}$ is greater than 1·8, the curve is, however, a straight line and cuts the axis at $H\rho = 6130$, where the direct determination gives $H\rho = 6180$ or $1{\cdot}41 \pm 0{\cdot}02$ MeV. This value agrees well with the value obtained by Lawson[2], $H\rho = 6150$, but disagrees with that obtained by Kurie, Richardson and Paxton[4] with the cloud chamber (1·7 MeV.).

Nuclear Disintegrations Produced by Cosmic Rays

SINHA has recently published[1] a remarkable cloud-chamber photograph of a four-pronged disintegration of an oxygen nucleus produced by a neutral cosmic ray particle. From the appearance of the tracks, he concludes that the two outer ones (tracks 1 and 4) are due to particles of a charge higher than that of an α-particle. The two inner tracks (2 and 3) appear to be due to doubly charged particles. Their end portions are crossed by thin ionization tracks. After

considering the possibility that this is due to an extremely rare chance coincidence, Sinha suggests that the thin tracks may be interpreted as pairs of (oppositely charged) electrons emitted from excited nuclei at the end of their paths. He emphasizes, though, that it is difficult to understand why the electrons should be emitted in diametrically opposite directions.

If we grant that tracks 1 and 4 are due to fast-moving nuclei with Z equal to or greater than 3, tracks 2 and 3 could be due only to singly charged particles (hydrogen isotopes), if conservation of charge is assumed in the disintegration of the oxygen nucleus ($Z = 8$). However, our present knowledge of the properties of the hydrogen isotopes leaves little room for the possibility that they may have excited states of sufficiently long life to emit electron pairs at the end of their paths.

If we still assume a causal relationship between the thin tracks and tracks 2 and 3—which will remain an open question until it is decided by further experiments—we are forced to conclude that a hitherto unknown process takes place. In such a situation we have only the most generally valid principles, like conservation of charge and momentum, as a guide. The simplest hypothesis compatible with these principles which would account for Sinha's picture appears to be the following. In the collision of a neutral cosmic ray particle with an oxygen nucleus, two new particles of opposite charge are created (2 and 3), and the oxygen nucleus broken up into two parts (1 and 4). To judge from their great ionizing power, the particles 2 and 3 have each double electronic charge and a mass which is considerably larger than that of two electrons. They are therefore intrinsically unstable, but apparently have a sufficiently long life, so that they do not decay until they have lost their kinetic energy. Each then decays into a pair of electrons, both negative in one case, and both positive in the other. Conservation of momentum requires that the decay electrons are emitted in diametrically opposite directions, and with equal velocities (equal specific ionization).

Disintegrations of nuclei by cosmic rays, or 'stars', have been studied by many observers in photographic emulsions. These stars appear to consist of proton and α-particle tracks, yet different observers disagree on the relative frequency of these particles[2]. When the number of particles in the 'star' is small, this type of disintegration may be pictured as a Bohr evaporation process[3]. However, where the number of singly or doubly charged particles approaches or exceeds[4] the atomic number of the original nucleus, it would seem necessary to assume the creation of new strongly ionizing particles. Sinha's picture may give a clue to the nature of these particles, which may have an ionizing power intermediate between that of a proton and that of an α-particle (for equal range). In this case they might have been identified with protons by some observers and with α-particles by others.

Relationship between Dielectric Constant of Liquids and Solids and Dipole Moments

It has been found that the molar electric susceptibility of liquids,

$$P = (\varepsilon - 1) \times M/d = 4\pi N(\alpha + \mu^2/kT),$$

where ε is the dielectric constant of the pure liquid and μ the moment. The derivation of this follows if we regard the dipole as needle-shaped. This assumption is inherent in the Debye equation for gases. In solids and liquids, owing to hindered rotation, molecular orientations are distributed according to the Boltzmann function μ^2F/kT, because the dipoles can become oriented only in two directions, along and opposite to the direction of the electrical field. This relationship is found to hold good for all normal liquids from hydrogen bromide ($0{\cdot}8D$) to nitrobenzene ($4{\cdot}2D$), and for solids such as hydrogen chloride, hydrogen sulphide, hydrogen bromide and hydrogen iodide which show molecular rotation at low temperature. In the case of associated liquids and divalent salts, kT is $\frac{1}{2}$. In ionic crystals the moment calculated from the dielectric constant has to be multiplied by the co-ordination number to give the same value as obtained by the molecular beam method. The results show that the alkali halides are 2/5 ionic or 'dipolar' in the gaseous and 1/15 in the solid state.

Details of this work will be published jointly with Miss Nagamani and Mr. Sathe.

Levine's Hypothesis of Maternal Iso-immunization

My recent letter on "Mutation and the Rhesus Reaction"[1] has provoked two replies. In one of them[2], Prof. J. B. S. Haldane raises an objection with which I hope to deal elsewhere at length when pressure of official duties is less exacting. In the course of the other[3], Prof. R. A. Fisher, R. R. Race and Dr. G. L. Taylor say that they "dissociate ourselves from the statement that 'Levine's hypothesis postulates a form of adverse selection . . .'". Levine's hypothesis postulates that the blood of an $Rh(-)$ mother who bears $Rh(+)$ offspring by an $Rh(+)$ father produces an antibody which plays havoc with the red cells of the fœtus. The result may be miscarriage, stillbirth or neonatal hæmolytic anæmia with possibly fatal consequences. Since such offspring are necessarily heterozygous, the hypothesis that erythroblastosis fœtalis, a condition lethal in a certain percentage of cases, is due to maternal iso-immunization also implies the existence of the adverse form of selection with which Haldane's letter mainly deals, as does the article of Wiener cited therein. Owing to present difficulties arising from dispersal of libraries for safe storage, I was not aware of the existence of Haldane's paper[4] in which he develops several conclusions which I have derived independently, though it now appears later. Otherwise I should have cited his own prior treatment of the type of adverse selection implicit in Levine's hypothesis.

The main point I was concerned to stress in the latter half of my letter may have eluded Prof. Fisher and his colleagues because it touches on a misunderstanding which, though very elementary, is also very prevalent in medical circles, with results of some public

interest. Again, it is one which Haldane deals with at length in his paper. For the reason stated, I was not aware that he had done so until after my own letter appeared. Levine and his co-workers do not explicitly assert that the combination $Rh(-)$ mother and $Rh(+)$ fœtus constitutes a *sufficient*, in contradistinction to a *necessary*, condition for the occurrence of erythroblastosis fœtalis; but their writings are certainly open to that interpretation, and I have recently met several eminent clinicians, including two responsible officers of blood transfusion depots, who interpret Levine's hypothesis in the former sense. Now the approximate incidence of $Rh(+)$ offspring of $Rh(-)$ mothers is easy to calculate. Indeed such calculations appear in preliminary notes of the pioneer work being done by the Galton Laboratory Serum Unit. They show that such offspring are vastly in excess of any recorded statistics of the incidence of neonatal hæmolytic anæmias, even after generous inflation of the figures by due allowance for fœtal deaths.

There are several possible reasons for this. I have suggested one, and could suggest several others. Haldane[4] offers the interesting hypothesis that women differ individually with respect to permeability of the placenta. It would therefore be interesting to know if an $Rh(-)$ *O* woman who had a history of miscarriage in a first marriage with an $Rh(+)$ *O* man would sustain the family tradition in a subsequent union with an $Rh(-)$ *A* man. In any event, there seems to be little doubt about the truth of either of two propositions: (*a*) that the genotype combination of the mother and offspring does not disclose a *sufficient* condition for the occurrence of erythroblastosis; (*b*) that it does disclose a *necessary* condition for a very high percentage of cases.

The distinction, if elementary, has some practical significance at the present moment, because voluntary donors at blood transfusion centres may be misled by popular or semi-popular expositions of Levine's important discovery, including his own in a recent issue of the *Journal of Heredity*. Indeed, my interest in its genetic implications was first excited by hearing of a Rhesus-negative young woman who had withdrawn her promise or offer of marriage when her donor fiancé proved to be $Rh(+)$. I cannot improve on Haldane's own statement of the practical issue in his paper on the adverse form of selection which Levine's hypothesis implies: "it is obviously futile to urge that all *rh.rh* women, some 14% of the total, should be prevented or dissuaded from marrying the *Rh.Rh* and *Rh.rh* men who make up the remaining 86%. Research on the etiology of high placental permeability is an urgent problem. If it is largely due to a particular gene substitution, the gene in question must be much rarer than *rh* and therefore a more suitable target for negative eugenics."

With reference to the statement that the Galton Laboratory Serum Unit now postulates seven alleles, of which "not more than four are Rhesus positive", it suffices to say this. If progress continues at this encouraging tempo, the *Rh* locus may yet prove to be as unstable as I have ventured to suggest.

Crossing-over in the Males of *Drosophila subobscura*

MEIOSIS in the males of the higher Diptera is characterized by absence of chiasmata. This means that as a rule genetical crossing-over occurs only in females. There are, however, a few exceptional families in *Drosophila melanogaster*[1,2] and *virilis*[3], the constitution of which can only be explained as due to crossing-over in the father. In these cases the exceptional offspring occurred in batches rather than singly. It was therefore supposed that crossing-over had taken place in one of the early spermatogonial divisions, though there is no cytological basis for this assumption.

I have found, in *Drosophila subobscura*, cytological evidence that crossing-over can take place in males during meiosis. Of three hundred testes from stocks containing 1–3 pairs of large autosomal inversions, one contained a lobule in late first anaphase, in which eight of the thirty-two nuclei in division showed single chromosome bridges, one a bridge and a fragment, and another two bridges. This is evidence that crossing-over had taken place in ten out of thirty-two cell divisions, because single crossing-over in inversions which do not include the centromere results in dicentric and acentric fragments. The dicentric fragments form bridges either at the first or second meiotic division, and the acentric fragments are lost.

Thus a male Drosophila still has the possibility of forming chiasmata. Normally, however, the meiotic chromosomes first emerge from a diffuse condition in the diakinesis stage of prophase; the pachytene stage where chiasmata are formed in a normal meiosis has never been seen. A slight alteration in timing, which affects all the cells in a lobule simultaneously, may permit chiasma formation, thus showing that the properties of the chromosomes have not changed radically. This results in the occasional appearance of a number of cross-over individuals in the progeny of a single heterozygous male.

Fluctuations in Seaweed

RECENTLY, several communications have appeared in NATURE relating to seaweeds, their properties and uses. It is apparent that their commercial potentialities are much more considerable than has hitherto been realized, and that this is not merely a temporary effect of war needs. Obviously, progress must depend on the continuance of adequate supplies, yet little has been said as to the need for the study of their distribution, conservation and protection in favourable localities.

There are, indeed, two opposing views among those who have any opinion in the matter. The one is a firm belief that supplies are 'inexhaustible'; the other, that they are, like land crops, subject to serious fluctuations unless proper precautions are taken. It may be well to consider how far these views are based on general impressions or founded on fact.

In his lecture to the Royal Society of Arts in 1884 on "The Economic Aspects of Seaweeds", the distinguished chemist, E. E. C. Stanford, stated that the supply of material (for commercial purposes) was "almost unlimited". In a much more recent, though undated, brochure, entitled "Manucol", it is claimed (p. 5) that "Certain marine plants form an inexhaustible source of raw material for alginate production". This view has doubtless been the more readily accepted, since at certain times and places vast quantities of weed are thrown up by the tide after rough weather. The frequent lack of means to utilize them to the full would give the impression of great surplus. It is known that important substances for plant growth, such as nitrates and phosphates, undergo seasonal fluctuations in sea-water, being much depleted after spring growth and regenerated naturally in the autumn. One source of replenishment is the soil and detritus washed down from land by streams. These findings, however, do not relate at present to places with the largest yield of seaweed, and the cumulative effect of the complete removal of many thousands of tons of seaweed periodically is quite unknown.

The alternative view is borne out by experience in regions where the utilization of seaweed has been for long a local industry of importance. For example, on the coasts of Brittany harvesting seaweed has been subject to strict regulation for more than a century, while in Japan, still more vigilance and supervision has been practised since the expansion of the seaweed industry into a considerable export trade, during the present century. An account given by Yendo to the Royal Society of Dublin in 1914 gives some idea of the reasons for these developments. It was found, for example, that with repeated harvesting, certain beds of Laminarias became overgrown with a rapidly spreading submarine flowering plant. The prostrate shoots of these plants had to be cleared by hand before the Laminarias could be gradually re-established. By proper attention between harvestings, this condition could be prevented, and instructions were issued and enforced in the areas concerned. Seaweed 'farms' for the cultivation of Fucus and Porphyra were also established and apparently brought to a high degree of efficiency.

There are also certain general considerations which point in the same direction. The large deposits of drift seaweed which occur from time to time are frequently not reported, much less understood. Laminarias flourish in quantity on submerged reefs away from human habitation. Organized attempts to utilize them, if leading to the growth of communities of any size, with the necessary sewage disposal, may have unforeseen effects. Moreover, seaweeds, like other plants, have their diseases, and crops must be spaced to allow for effective regeneration. Other circumstances, such as the accumulation of oil residues from shipping, or the shift of tides, may alter productivity in particular areas. At present we have no effective means of estimation of quantity in relation to quality or to seasons.

On these and many other questions arising from the commercial exploitation of seaweeds, we have little or no information. Only a long-term policy of planned investigation can provide answers to some of them, and it has been well said that such investigation should be teamwork, including marine zoologists as well as botanists. It should not be forgotten, however, that knowledge of seaweeds is at a relatively low level, even on the systematic side. Much remains to be done before we shall have a real understanding of their life and their reactions to environment.

I understand that already a falling off in the amount of seaweed has been alleged by collectors in certain very productive regions. Is this due to faulty memories, or to lack of adequate means of estimation of quantity (comprising depth as well as extent, on the shore)? Or is it, on the other hand, a timely warning that the estimation and conservation of natural sources is already urgent? If the latter, much investigation will be needed to establish the principles upon which such a policy should be based.

Spore-forming Bacteria causing Soft Rot of Potato and Retting of Flax

BACTERIAL soft rot of vegetables and the retting of flax are both due to decomposition of the pectin complex in the middle lamella, in the former case resulting in a loss of cohesion between the cells of the vegetable in the area invaded by the causal organism, and in the latter case resulting in a dissolution of the layer which binds the fibre bundles to the remainder of the cortex. It seems likely, therefore, that some bacteria may be furnished with the necessary enzymes to enable them to bring about both these changes.

In the course of an investigation carried out at this laboratory on the process of retting flax in tanks, large numbers of samples of retting liquor and of flax, taken at various stages during different processes of retting, were submitted to bacteriological examination. Tubes of nutrient broth, each containing a small cube of sterile potato, removed aseptically from the interior of a tuber, were found to be a suitable medium for testing for bacteria which produce soft rot of potato. Successive ten-fold dilutions of the retting liquor, or of an extract of the flax, were made in sterile Ringer solution, and duplicate quantities of 1 ml. from each dilution were inoculated into separate tubes of the potato medium, which were then incubated at 30° C. and were examined at intervals during a period of fourteen days. Soft rot of potato was detected by prodding with a stiff nichrome wire. It was found that, at or near the completion of the retting, soft rot was consistently produced by high dilutions of the liquor or of the flax extract, the 'count' of the causal organisms varying to some extent with the method of retting, but usually being between 10^4 and 10^8 per ml. of liquor or per gram of moist flax. Tests with similar media containing vegetables other than potato showed that bacteria causing soft rot of turnip were also consistently present, but that carrot or parsnip gave uncertain results.

It appeared from a large number of tests, made with tubes in which the potato had been rotted, that in the flora of retting liquor or of retted flax, ability to cause soft rot of potato was confined to spore-bearing bacteria, that the anaerobic spore-bearers were usually predominant among the causal organisms, but that aerobic spore-bearers with this characteristic were sometimes present in appreciable numbers. This observation may be compared with Ruschmann's statement[1], which is borne out by the literature, that

all aerobic and anaerobic retting organisms are spore-formers.

From two different rets a spore-bearing aerobic bacillus was isolated in pure culture; this produced soft rot in potato under laboratory conditions. The morphology and reactions—formation of acid and acetoin, but no gas, from dextrose, rapid liquefaction of gelatin, digestion of milk, and strong diastatic power—of the two cultures were identical and conformed with those of *B. subtilis*. Their identity with this organism was confirmed by Dr. T. Gibson of Edinburgh, to whom subcultures were sent.

Testing the ability of a pure culture to ret flax is rendered difficult by the fact that the flax used as a substrate may be appreciably altered in character if it is sterilized by heat. To obviate this difficulty an enzyme powder, capable of acting in the presence of an antiseptic which inhibits bacterial growth, was prepared from each of the two strains of *B. subtilis* by the following method, which is similar to that described by Dox[2].

A mass growth was obtained by seeding the surface of potato-mush agar sloped in ten 1-litre bottles. After incubation for two days at 30° C., the growth was washed off with water and the aqueous suspension was filtered through a Buchner funnel. The residue on the filter paper was ground in a large volume of acetone and left immersed for ten minutes. The acetone was filtered off at the pump and the residue was similarly treated, first with acetone for two minutes and finally with ether for three minutes. The residue after filtration was dried in a thin layer at 37° C. for two to three hours, and was then ground to a fine greyish-yellow powder which was tested as follows:

(1) 0·2 gm. of the powder was ground with 5 ml. of distilled water and the suspension was transferred to a test tube. Several thin disks of freshly cut potato (approximately 1 cm. in diameter and 1 mm. in thickness), and 0·2 ml. of toluene, were added to the suspension, which was thoroughly shaken. A control tube without the enzyme powder was prepared at the same time and both tubes were incubated at 30° C. When examined after 18 hours, the disks of potato in the enzyme preparation showed complete soft rot, disintegrating easily when manipulated with a stiff wire. Disks in the control tube were unaltered.

(2) Flax stems were cut into uniform lengths of about 4 in., and were packed tightly into a glass cylinder about 1 in. in diameter. A suspension containing 2·5–3 gm. of the enzyme powder and 2 ml. of toluene in 50 ml. of distilled water was poured into the cylinder until the flax was completely immersed. A control cylinder without the enzyme powder was prepared in the same way, and both cylinders were incubated at 30° C. Progress of retting was followed at intervals by means of the 'loose core' test, and a small quantity of toluene was added daily to each cylinder. The flax immersed in the enzyme preparation was completely retted in three days, the flax in the control cylinder being unchanged.

These experiments show that *B. subtilis* produces enzymes which rot potato and ret flax. The fact that the process of retting in tanks on a large scale is accompanied by the growth in large numbers of spore-forming bacteria which produce soft rot of potato suggests that they may also be largely responsible for the retting. It may be noted that ability of spore-forming bacteria to cause soft rot of potato, which Dowson[3] recorded for *B. polymyxa*, is certainly not, under laboratory conditions, confined to that species.

Reported Asymmetric Synthesis of Santonin

THE announcement that santonin containing approximately 93 per cent of the *lævo*-rotatory variety (naturally occurring santonin is *lævo*-rotatory) has been obtained by Paranjape, Phalnikar, Bhide and Nargund[1] during the synthesis of santonin without apparently any asymmetric influence at any stage of the synthesis is of unusual interest. The realization of such a result cannot be excluded on the evidence given. On the other hand, it is contrary to all analogous experimental results so far recorded that methylation of an externally compensated and optically inactive compound should proceed at different rates on the *lævo*- and *dextro*-constituents of the externally compensated substance even when the asymmetric carbon atom is involved. It is possible, however, to conceive cases when a difference in reaction velocities of the *lævo*- and *dextro*- varieties of an externally compensated compound may be realized.

So far as present conditions permit, it would be useful if as large a number as possible of experienced investigators should repeat the methylation of 2-formyl*cyclo*hexanone under various conditions, and determine whether or not the resulting 2-methyl-2-formyl*cyclo*hexanone is or is not optically active. If any positive evidence is obtained the statistical analysis of the results would be interesting.

Microbiological Assay of Riboflavine

PROF. R. H. HOPKINS[1] has added to Dr. Barton Wright's and Mr. Booth's[2] reply to the comments made by Happold[3] on the microbiological technique for the assay of riboflavine and has included a criticism of the work published by us[4]. Both communications concentrate on the point made by us regarding the amount of calcium in the medium, while ignoring other points of criticism which we made. Barton Wright and Booth state that the calcium effect is due to buffer action, this being incorrect, while Hopkins, relying on the papers of Holt, La Mer and Chown[5] on calcification in bone and on the solubility product of $Ca_3(PO_4)_2$ in water or in serum, states that the calcium concentration could not be influenced appreciably by added calcium chloride at *p*H 6·6–6·8. It should be mentioned that Holt *et al.* state that the solubility product is affected enormously by the presence of other salts and that a complex solution of amino-acids is very different from serum (protected by these workers against bacterial proteolysis). They also state "the precipitation of tertiary calcium

phosphate occurs so slowly that solutions of this salt may remain supersaturated for many days".

We are not concerned with theoretical considerations, we can but record our findings made frequently and separately by us and using an acid hydrolysate of casein, similar in all respects to that of J. H. Mueller[6] and to that of Snell and Strong[7]. We have also indicated, from a review of the literature, that mineral requirements may be modified by the pattern and amount of growth factors added to the medium.

But Prof. Hopkins asks a question by implication: if little or no precipitation occurs immediately after the addition of $CaCl_2$ to the cold sterile medium, what happens after seventy-two hours? In our experience (in uninoculated controls), very little. It must be remembered also that we are not dealing with simple solutions; there is a rich variety of amino-acids present in the medium, cells are growing rapidly and glucose is being metabolized. Phosphates are utilized in both these processes and are removed from the medium, and finally the pH of the medium falls. All these factors will tend to increase the solubility of calcium, which in our experiments is never precipitated.

Cellulose Acetate Mounts for Rock and Mineral Fragments

EMBEDDING rock or mineral particles in a uniform thin sheet of cellulose acetate facilitates their optical examination, transport and storage, especially during the field study of graded concentrates derived from detrital or crushed rocks.

More than a hundred times the quantity of such particles can be mounted together than is possible in any normal Canada balsam/glass mount, while preserving all significant microscopical advantages of the latter. This fact enables more accurate quantitative mineralogical analyses of certain sands to be made, for example, by accommodating in a single mount the whole heavy-mineral concentrate from a bulk-sample of greater volume than it has been convenient to study in most cases hitherto. Areas of the film containing grains of critical importance can be marked with ink, greasy crayon or gummed paper masks, or removed for special treatment with scissors, a knife or razor blade.

The substance of the sheet is colourless, transparent and isotropic when unstrained, with a refractive index of about $N_D^{20°}$ 1·4, depending upon the exact composition of the dispersion. It is light in weight, very flexible, insoluble in water and does not crease, crack or tear, even when handled comparatively roughly. In composition it is identical with that of the laminar moulds used by me for studying the finer structures of rock, mineral and metal surfaces[1].

To prepare such a mount, a cold dispersion of cellulose acetate in one part by volume of tetrachloroethane and two parts by volume of 'Cerric Thinner T.10' (Cellon, Ltd., Kingston-on-Thames), containing about 20 per cent (of the weight of cellulose acetate) of a plasticizer such as triphenylphosphate or dimethyl-phthalate, is flowed over a levelled sheet of clean plate glass, say, 23 cm. × 10·5 cm. × 0·6 cm., to a depth of 0·1–0·15 cm., the latter depending on the maximum diameters of the particles concerned. Immediately this has been done, the sieved rock or mineral powder, either before or after separation into fractions, is moistened with tetrachloroethane and shaken as evenly as possible over the dispersion layer, into which it sinks.

In about eight hours the compact film remaining after volatile parts of the dispersing medium have evaporated has a thickness about one tenth that of the original fluid layer. The film is then stripped from the glass, labelled and its edges trimmed with scissors, before being examined optically.

A trace of some suitable dye, when added to the parent dispersion, serves to distinguish any particular batch of mounts by its tint. Rectangular films, 23 cm. × 1·5 cm. × 0·01 cm., are of convenient shape and size for microscopical examination and can be stored or posted in standard foolscap paper envelopes without further protection. With regard to the permanence of these mounts, experience has shown that they have developed no appreciable discoloration, brittleness or shrinkage after three years of storage in such envelopes.

High-Angle Edge Flaking of Flint

MR. D. F. W. BADEN-POWELL's criterion for intentional flaking[1] is invalid, for when applied to implemental forms from Eocene deposits it gives a false answer.

Mr. J. Reid Moir's contention that series of adjacent scars form a criterion of human work fails when applied to similar series of Eocene date. My own criterion is based on observed facts and not, as Baden-Powell suggests, on an assumption that primitive man was not likely to flake at obtuse angles.

Baden-Powell states that flaking at about 90° is necessary for removing flakes from Aurignacian and Magdalenian cores. This is not a fact, for it is well known that such cores are in their final or 'reject' state. They began with an acute angle which increased as flaking proceeded to about 90°, which is the limit of easily controlled flaking. The platform is then again made acute or the core is rejected.

Primitive man adopted flaking at acute angles because it is easy, is under good control, and yields acute cutting edges. Obtuse angle flaking possesses none of these advantages.

In reply to Mr. Henry Bury[2], I would point out that natural forces were sufficiently active to leave abundant traces of crushing, abrasion and striation on the Tertiary flints.

In the series of nine human industries I gave in *l'Anthropologie*[3] from which Bury quotes, the Abbevillian, one of the oldest industries, is placed next to the Campignian, which is of Neolithic age. In the series of sixteen industries published else-

where[4], the non-correspondence between age and content of obtuse angles is clearly evident. The "Cromerian" industry was not included in my list, because recent work on the site by S. H. Warren throws grave doubts on its origin.

The Zambesi flakes are too rolled to allow of angle measurement. They are clearly of human origin and the character of the flaking is normal.

ALFRED S. BARNES.

Dormers,
Farnborough, Kent.

[1] Baden-Powell, D. F. W., NATURE, 152, 663 (1943).
[2] Bury, H., NATURE, 152, 664 (1943).
[3] Barnes, A. S., *l'Anthropologie*, 48, 221 (1938).
[4] Barnes, A. S., *Amer. Anthrop.*, 41, 110 (1939); *Bull. Soc. Prehist. Franc.*, No. 1, Fig. 6, 10 (1939).

MY letter in NATURE of December 4 raised three main issues.

(1) If, as Mr. Barnes asserts, Kentish eoliths, etc., were formed by soil movement in Tertiary times, why, I asked, did the still more active movements of the Pleistocene produce no similar results? To tell us that natural forces left "abundant traces of crushing, abrasion and striation on the Tertiary flints" in no way answers my question.

(2) Seeing that the percentage of high-angle scars rises rapidly "as we pass from the later and more skilled to the older and rougher work", I suggested that a still further rise in Pliocene times was not impossible. Barnes replies that there is no correspondence "between age and content of obtuse angles"; but, on his own figures, there is. There may be recrudescence of rough work in late industries (Campignian, etc.), with local increase in the number of obtuse angles; but no early industry shows a low number.

(3) I thought that further information about the Zambezi implements might possibly affect Barnes's conclusions. I am interested to learn that he finds them "clearly of human origin", as my impression is that some of them (not figured) are very like Kentish eoliths. That remains to be seen.

HENRY BURY.

The Gate House,
Alumdale Road,
Bournemouth.

MR. A. S. BARNES says that Mr. J. Reid Moir's "criterion of human work fails when applied to similar series of Eocene date". This is not true, at least for the Bull-head Bed at the base of the Eocene in Suffolk, which was specially investigated by Moir[1] in order to settle this question. Moir came to the conclusion that there are essential differences between fractured flints of Eocene age and those of later date described as eoliths, although occasional Eocene flints can be found which show a superficial resemblance to flints flaked intentionally.

With regard to the use of steep flaking by Palæolithic man, I agree with Barnes's criticism of a statement in my letter in NATURE of December 4 that Magdalenian flakes can be removed from the core "only" by steep flaking. Obviously some of the flakes in Upper Palæolithic work were removed at lower angles than others; but the fact remains that Magdalenian man could, and often did, remove usable flakes at high angles. I am glad that Barnes admits that these flakes are due to human and not natural agency. Quite apart, therefore, from the steep flaking used for the butt ends of Acheulean axes and for Aurignacian edge-work, it seems established that at least some high angles are also seen on various Upper Palæolithic cores. This does not invalidate the interesting suggestion in Bury's letter in NATURE of December 4 that the rise of percentage of steep flaking with antiquity may be significant; it does, however, prove that steep flaking cannot be taken as a criterion of intentional work.

Veterinary Education in Great Britain

THE leading article in NATURE of January 8 on veterinary education provides me with an excuse for mentioning some of the obstacles I see in our path. The present is a good time for discussion; for definite decisions, it is the worst time that has occurred during my rather long life. Never has the future of the nation, or the nature of the work lying ahead of the veterinary surgeon, been so unpredictable as it is to-day.

The Ministry of Agriculture looks forward to a need for a very much greater output of veterinary surgeons —I cannot see why. No doubt, it expects to increase the numbers and the work of whole-time inspectors, but this must be largely at the expense of the part-time and independent men; and it would appear to me that the general agricultural policy pursued pre-war—as much grass as possible and bring in concentrates from abroad—was designed to support a larger head of sheep and cattle than can be kept under any other system. Ploughing up grass means fewer, not more animals.

The Council of the Royal College of Veterinary Surgeons has a curriculum committee; I do not agree with many of its conclusions, but probably that is because I am old-fashioned. I do hope we are not likely to have a curriculum rammed down our throats by Government.

The present curriculum is well designed for the production of large-animal practitioners. Besides these, we have to provide small-animal practitioners; inspectors and research men for the Ministry of Agriculture; executive and research men for the Colonial Service; Royal Army Veterinary Corps men; and a diminishing number of municipal and county officials. The qualifications needed are very different, and it will always be impossible to train our students so as to be efficient for all these purposes, on graduation.

It will be the part of wisdom if we carry on with the *status quo ante* until after the War, taking no irrevocable steps, making no changes of constitution in the colleges.

When we see the number of each different kind of graduate that will be called for, we can try to arrange a suitable curriculum, reinforced by post-graduate classes; but we can never give experience. The most important part of veterinary education will always come after appointment.

ANNUAL MEETING OF CHINESE SCIENTIFIC SOCIETIES

A JOINT annual meeting of the Science Society, the Zoological Society, the Botanical Society, the Meteorological Society, the Mathematical Society and the Geographical Society of China was held at Pehpei, Chungking, during July 18–20 of last year. Despite the hot weather which prevailed then, 240 members attended the meeting, which was presided over by Dr. Wong Wen-hao. In his opening address, Dr. Wong said that a joint meeting like this is especially desirable in war-time, in that it is economical in time, labour and expenditure and will enhance co-operation between societies which are related in character. In view of the present tendency to overlook the study of pure science, Dr. Wong remarked that truth is what science values most, regardless of whether or not practical use can be derived from it; and he urged the pure scientists to stand firm. As a geologist and the Minister of Economic Affairs, he illustrated with first-hand examples how what appeared to be pure geology at first turned out later to be of much practical value in the detection of China's natural resources. The address of the Generalissimo was then read, in which he declares: "Pure science is the foundation of all applied sciences. If we wish to stand up among the modern great nations there must not be the slightest tardiness in the prosecution of pure science" (see also NATURE, Aug. 14, 1943, p. 180). While most of the official emphasis has been laid on the practical side in the recent tide of national industrialization, it will do the nation good to remind people of the significance of pure science.

In the business meeting held in the first afternoon, Dr. J. Needham was elected honorary member of the Science Society of China, in appreciation of his distinguished academic work and his service in promoting co-operation between Chinese and Western science, which had been so effectively carried on during the previous six months.

The six societies spent two mornings in communicating original papers dealing with their respective sciences; more than three hundred papers were read. Brief abstracts of these papers will be published shortly, in Chinese with additional English titles.

One of the two remaining afternoons was devoted to a discussion on "Science and National Reconstruction", with special reference to the problem of how science is to be promoted in China. Opinions were formulated on the following four points, which were presented to the Chinese Government for immediate adoption.

(1) The Government is requested to provide a large fund in the forthcoming national budget for, and only for, the furtherance of scientific research and of the scientific education of the masses.

(2) The personnel and equipment of the leading science institutes, such as those of Academia Sinica, must be materially augmented.

(3) The Government must endeavour to establish co-operation between the scientific workers on one hand and officials in charge of national planning on the other, so that the resulting plans may be more practical and fruitful.

(4) While the Government is considering sending a large number of young men of science abroad, it is deemed appropriate that such opportunities should be extended to mature scholars also. Here again, the Government is requested not to neglect pure science in favour of applied sciences and technology.

The last afternoon of the meeting was reserved for a discussion on "International Science Co-operation". To familiarize the audience with some idea of the subject under discussion, four specialists were asked to talk about the co-operative measures hitherto taken, along with the sound results accomplished therefrom, in agriculture, industry, meteorology, and medicine and public hygiene. Dr. Needham's address, entitled "International Science Co-operation in War and Peace", was read next by Dr. H. C. Zen, president of the Science Society of China. In this address, Dr. Needham reviewed the present position of co-operation between Chinese and Western science and the problems arising on the scientific side of the war effort of the United Nations in the Asiatic theatre; he urged, above all, that a science co-operation service should be made a regular part of the United Nations Relief and Rehabilitation Administration. The meeting was unanimous that international science co-operation, founded on international understanding and goodwill, is worthy of striving for. Indeed, Chinese men of science seek co-operation with no less enthusiasm than their friends of the West.

A scientific exhibition intended for the general public has been arranged by the learned societies of China during the present session.

DIRECTIVE AERIALS FOR RADIO COMMUNICATIONS

THE second discussion evening of the current session of the Wireless Section of the Institution of Electrical Engineers was held on January 18, when Mr. J. A. Smale introduced the subject of "Comparative Merits of Different Types of Directive Aerials for Communications". At the outset, it was made clear that the main objects of using directive aerials are to increase the field strength of the signal at the receiving station without increasing the power radiated by the transmitter, and to improve the ratio of signal to noise and interference at the receiving site; another desirable aim is to minimize interference with other users of the ether.

In long-distance communication, interest is confined mainly to wave-lengths between 13 and 100 metres; the maximum obtainable gain, in general, requires one linear horizontal dimension of some 10 wave-lengths, and, while this is realizable up to about 30 metres, it tends to impracticability at the upper end of the wave-length range. In the above range of wave-lengths, transmission is effected by one or more reflexions from the ionosphere, the characteristics of which give to the ray paths various degrees of inclination in the vertical plane. Consequently, aerials have to possess directivity in this as well as in the horizontal plane, and in some types these two directivities are dependent on one another.

The two main aerial systems used are of the broadside and linear or end-fire types. In general, the end-fire type have their horizontal and vertical directivities interdependent; the maximum concentration in the horizontal plane results in very low angles of radiation in the vertical plane, so that for short-distance circuits requiring higher angles no satisfactory compromise is possible. In the case of broad-

side arrays, individual control of directivities is valuable. A high degree of directivity in the vertical plane with broadside arrays, however, requires a height of several wave-lengths. As the wave-length increases, this height and the support of reflector as well as radiator curtains require fairly massive masts and corresponding foundations. The choice of aerials is influenced to a considerable degree by capital and maintenance costs, and availability of land, as well as by the technical considerations which lead to an overall improvement in the efficiency of the radio communication circuit.

Some of the earlier beam systems were built for very high directivity in the horizontal plane; but experience has shown that this may be overdone, since the reflecting medium is not sufficiently stable and accurate. and conditions can obtain when a transmitted beam, if too narrow, may be deflected right off the receiving aerials.

Similar structures can be used for transmission and reception, but the requirements are not necessarily the same. In general, the maximum forward gain is the chief requirement of transmitting aerials: while at the receiving station it is not so much a high signal-level that is required as a good discrimination of the signal in relation to the prevailing noise-level. During the period of maximum sunspot activity backward round-the-world echoes are troublesome, and aerials should have the maximum front-to-back ratio. Experience shows that this is more easily obtained with broadside arrays. This is true with normal broadside arrays; but even better ratios are possible if the aerial is erected off direction and electrically swung on to the forward direction; the result is that backward radiation is swung away from the great-circle bearing.

In the case of receiving aerials this applies also, but the chief requirement is the correct shape of polar reception diagram rather than gain, at least on wave-lengths greater than, say, 20 metres. With modern receivers the limiting factor above this wave-length is not input-signal level but signal-to-outside-noise ratio. In this case the power inefficiency caused by terminating resistances at the non-fed end of 'end-fire' arrays is unimportant; consequently, relatively simple and cheap aerials of the horizontal fish-bone type are adequate, take up small space, and on a given area of land can be multiplied for diversity reception. This type of aerial can be arranged for almost any degree of compromise between end-fire and broadside.

During the discussion, considerable attention was given to the rhombic aerial system, which has the advantage of retaining a reasonable directivity over a wave-length range of about two-to-one. Some of this versatility is lost when several rhombics are used in series in order to secure greater efficiency, but on the other hand greater control of the vertical radiation can be obtained, and this may be a distinct advantage in some cases.

The relative merits of horizontal and vertical polarization in the emitted radiation were discussed by one speaker, who stated that in some experiments with broadcasting transmitters, horizontal polarization had given the best results. It was agreed that a considerably wider horizontal distribution is used in broadcasting than in point-to-point communication, but not necessarily a wider diagram in the vertical plane, because the vertical angle to be covered is often of the same order in the case of communication services and broadcasting.

The chairman directed attention to the widespread interest aroused by the discussion, which showed that the subject is one of great importance to the engineer responsible either for long-distance broadcasting or point-to-point communication services.

REVISED FORMS OF THE CALENDAR

COLONEL C. A. GILL has published a small book entitled "The Reform of the Calendar—a Measure of Social Security" (Reigate: Ancient House Bookshop. Pp. 36. 1*s*.), which contains the proposals for a British Calendar. On p. 26 this Calendar is shown in full, and it agrees with the World Calendar (shown on p. 15), except that the days termed the 365th and 366th days are to be included as an eighth day in the last week of June and December respectively. It is suggested that the 365th day, June 31, should be called Mid-Year Day, and the additional day in leap years, bearing the date December 31, should be called Leap-Year Day.

A prime consideration in fixing the date of bank holidays should be the season of the year when they are most beneficial to the health of the community, and the following proposals are made, the advantages of which will be seen when it is remembered that the first day of each month commences with Sunday. A bank holiday should continue to be associated with Easter, but the date of the Eastertide holiday should have April 9 included. As Easter Sunday falls on April 8 in about 40 per cent of years, this arrangement will increase the length of the Eastertide holidays to four clear days on many years, owing to the inclusion of Good Friday. If Saturday, April 7, and Monday, April 9, were declared bank holidays, the dates of all secular events which now vary annually with the date of Easter Sunday could then take their time from the fixed bank holidays in April. It may be pointed out that April 8 is the date proposed by the World Calendar Association for Easter Sunday—a proposal which may some day materialize.

Other bank holidays which are suggested are Saturday, May 25, and Monday, May 27, irrespective of the date of Whit Sunday. Saturday, June 30, and Mid-Year Day, June 31, if declared bank holidays, would provide a three-day holiday at the end of June, Sunday, July 1, being, of course, included. The bank holiday on the first Monday in August falls on August 6 under the new scheme, and it is proposed to continue with this arrangement, Saturday, August 4, being also a bank holiday. Saturday, September 2, and Monday, September 4, would be bank holidays. As December 25 falls on a Monday, a holiday on Boxing Day with the previous Sunday and half Saturday would provide $3\frac{1}{2}$ days' holiday at Christmas.

Another revised calendar has been proposed by Lieut. Willard E. Edwards under the title "The Edwards Perpetual Calendar" (printed by the *Honolulu Star-Bulletin*, Ltd.). In this, each week begins with Monday, and anniversaries and holidays always fall on the same day of the week. Each quarter has 91 days, and New Year's Day is set apart as a holiday and is followed by Monday, January 1, thus preserving the year of 365 days and the continuity of dates each year. In the case of a leap year, the first day of the second half of the year is Leap-Year

Day, a second holiday apart from any week or month, and is followed by July 1. April 14 is the date for Easter, which is partly in accordance with the Act of Parliament in 1928, providing for the stabilization of Easter between April 8 and 15. Friday, the 13th, is completely eliminated from the Calendar, thus removing the grounds of the superstition that exists concerning this date and day. Sunday becomes the seventh day of the week, and agrees more with the Biblical Sabbath or the psychological conception of the week. All future dates can be computed without the aid of a printed calendar by remembering that the first month of each quarter always begins on Monday, the second on Wednesday, and the third on Friday, the number of days in the corresponding months being 30, 30, 31.

It is claimed that this Calendar not only introduces simplicity regarding anniversaries and holidays, but also removes many complications in the commercial world, as there are 26 working days in each month and 91 days in each quarter.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Saturday, February 19

BRITISH ASSOCIATION OF CHEMISTS (at the Café Royal, Regent Street, London, W.1), at 2.30 p.m.—Twenty-sixth Annual General Meeting.

Monday, February 21

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Dr. E. B. Bailey, F.R.S.: "Natural Resources of Great Britain", 1: "Minerals". (Cantor Lectures, 1.)

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 5 p.m.—Lady Broughton: "Greenland, Mexico and Yucatan" (Kodachrome Films).

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Discussion on "The Use of Electricity in the Equipment and Testing of Aircraft" (to be opened by Mr. C. G. A. Woodford).

Tuesday, February 22

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 1.30 p.m.—Dr. Luis Araquistáin: "Some Survivals of Ancient Iberia in Modern Spain".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Dr. J. Ramsbottom: "Fungi and Modern Affairs", 2: "Fungi as Agents of Disease and Destruction".*

EUGENICS SOCIETY (at the Royal Society, Burlington House, Piccadilly, London, W.1), at 5.30 p.m.—Mr. B. S. Bramwell: "The Order of Merit—the Holders and their Kindred".

INSTITUTION OF CIVIL ENGINEERS (at Great George Street, Westminster, London, S.W.1), at 5.30 p.m.—Mr. V. A. M. Robertson: "The Engineering Evolution of London Transport".

Wednesday, February 23

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. Hugh Lyon: "Education To-day and To-morrow", 5: "The Future and Functions of the Boarding School".

INSTITUTION OF ELECTRICAL ENGINEERS (WIRELESS SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. B. J. Edwards: "A Survey of the Problems of Post-War Television".

Thursday, February 24

BRITISH SOCIETY FOR INTERNATIONAL BIBLIOGRAPHY (at the Science Museum, Exhibition Road, South Kensington, London, S.W.7), at 2.15 p.m.—Annual General Meeting; Mr. S. W. Gibson: "The Library and Information Department of a Large Engineering Firm"; Dr. S. C. Bradford: "The Universal Decimal Classification its Origin and Purpose, Structure and Use".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Sir Jack Drummond: "Food Fads and Food Fallacies".*

KING'S COLLEGE (in the Department of Electrical Engineering, Strand, London, W.C.2), at 3 p.m.—Mr. S. D. Thorp: "Generator Protection".*

ROYAL AERONAUTICAL SOCIETY (at the Institution of Mechanical Engineers, Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Dr. D. M. A. Leggett and Mr. H. Davidson: "Structural Features of German Aircraft".

BRITISH INSTITUTION OF RADIO ENGINEERS (LONDON SECTION) (at the Institution of Structural Engineers, 11 Upper Belgrave Street, London, S.W.1), at 6.30 p.m.—Mr. C. E. Tibbs: "A Review of Wide Band Frequency Modulation Technique".

BRITISH ASSOCIATION OF CHEMISTS (ST. HELENS SECTION) (in the Lecture Room, Radiant House, Cotham Street, St. Helens), at 7.30 p.m.—Mr. H. Cole: "The Literature of Alchemy".

Friday, February 25

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5 p.m.—Mr. E. Rock Carling: "The Medical and Surgical Achievement of Soviet Russia in War".*

INSTITUTION OF MECHANICAL ENGINEERS (at Storey's Gate, St. James's Park, London, S.W.1), at 5.30 p.m.—Discussion on "Troubles, Breakdowns and their Cure".

Saturday, February 26

SCHOOL NATURE STUDY UNION (at the Central Club, Y.W.C.A., Great Russell Street, London, W.C.1), at 2.30 p.m.—Thirty-eighth Annual Conference; at 3 p.m.—Prof. W. B. R. King: "The Evidence of Fossils".

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

SPEECH THERAPIST to serve the Crewe and Cheshire Education Committees jointly—The Director of Education, Education Offices, Imperial Chambers, Prince Albert Street, Crewe (February 23).

HEAD OF THE DEPARTMENT OF MECHANICAL AND AUTOMOBILE ENGINEERING, and HEAD OF THE DEPARTMENT OF ELECTRICAL ENGINEERING, at the Doncaster Technical College—The Chief Education Officer, Education Offices, Wood Street, Doncaster (February 24).

LABORATORY ASSISTANT IN THE DEPARTMENT OF BOTANY—The Secretary, Bedford College for Women, Springfield, Sidgwick Avenue, Cambridge (February 26).

PSYCHIATRIC SOCIAL WORKER (full-time)—The Director of Education, Education Offices, Middlesbrough (February 26).

LECTURER IN MATHEMATICS—The Registrar, Technical College, Sunderland (February 28).

SENIOR LECTURER IN MATHEMATICS—The Clerk to the Governors, South-East Essex Technical College and School of Art, Longbridge Road, Dagenham, Essex (February 28).

WOMAN LECTURER IN THE DEPARTMENT OF EDUCATION, qualified to lecture in EDUCATIONAL HYGIENE—The Registrar, King's College, Newcastle-upon-Tyne (February 29).

ELECTRICAL ENGINEER (to instruct and supervise General Electrical Installation Work, Maintenance and Repairs), and an ELECTRICAL MAINTENANCE FOREMAN (to assist with Installation and Maintenance Work), for a Modern Iron and Steel Works in Turkey—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. D.755.XA) (March 1).

LECTURER (man or woman) in the DEPARTMENT OF GEOGRAPHY—The Secretary, Bedford College for Women, Regent's Park, London, N.W.1 (March 1).

MONTAGUE BURTON PROFESSORSHIP OF INTERNATIONAL RELATIONS—The Registrar, The University, Oxford (March 4).

ENGINEER AND MANAGER of the Walsall Gas Undertaking—The Town Clerk, The Council House, Walsall (March 6).

LECTURER IN ELECTROTECHNOLOGY in Santa Maria, Chile—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. D. 763.XA) (March 8).

LECTURER (man or woman) IN BOTANY, and a DEMONSTRATOR (man or woman) in BOTANY—The Secretary, Bedford College for Women, Regent's Park, London, N.W.1 (March 8).

PROFESSORSHIP OF CHEMICAL TECHNOLOGY—The Vice-Chancellor, University of Madras, Triplicane P.O., Madras' India (March 31, by cable; at the same time advise the Office of the High Commissioner for India, General Department, India House, Aldwych, London, W.C.2).

UNIVERSITY LECTURER IN ANTHROPOLOGY—The Secretary of the Appointments Committee, Faculty of Archæology and Anthropology, Museum of Archæology and of Ethnology, Cambridge (April 15).

DIESEL MECHANIC FOR MINING PROPERTY on the Gold Coast—The Secretary, Overseas Manpower Committee, Ministry of Labour and National Service, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. 310).

ENTOMOLOGICAL FIELD OFFICERS by the Government of Kenya Medical Department—The Secretary, Overseas Manpower Committee, Ministry of Labour and National Service, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. 1270).

LIBRARIAN of the British Library of Political and Economic Science—The Acting Secretary, London School of Economics, The Hostel, Peterhouse, Cambridge.

WORKS MANAGER for the Sierra Leone Government Railway—The Ministry of Labour and National Service, Appointments Department, Sardinia Street, Kingsway, London, W.C.2 (quoting Reference No. O S.30).

PLANNING AND THE MACHINERY OF GOVERNMENT

THE fundamental questions of the machinery of government and its development to serve the growing burdens which are laid upon it by the increasing integration of political and economic affairs are being repeatedly emphasized by the problems of war and reconstruction alike. These fundamental issues have been admirably stated in a report which has been issued by the Select Committee on National Expenditure. Dealing essentially with "War Production and Methods of Settling Prices for War Stores", the fourteenth report of the 1942–43 session contains a short section on the machinery of government in which the wider issues are lucidly stated. The section follows logically on an earlier report, the sixteenth of the 1941–42 session, and should be carefully considered in connexion with the reorganization of either the Civil Service or of ministerial structure and responsibility itself.

The execution of Government policy, quite apart from what has to be done in total war, or in the special conditions of post-war reconstruction, has come to be a major factor in the economic life of the country, directly or indirectly affecting every branch of its activities. This change must be taken into account in the whole organization and working of the Civil Service, including its recruitment and training, and the report refers to the earlier recommendation of the Committee regarding opportunities for bringing Civil servants into closer contact with industrial practice. Primarily, it is the impossibility of properly handling departmental activities in isolation from each other or without regard to their reactions on the general economic activity of the country that has impressed the Select Committee, through its whole series of inquiries into war production, with the need for some measure of supra-departmental supervision. Each of the Supply Departments has as its primary objective the fulfilment of its own production programme; but the national interest demands that the national programme as a whole should be kept in view, and that the delivery of the goods required for the programme should be achieved in the right proportions and with the minimum demand on manpower, materials, machinery, transport, fuel and power.

Since the Cabinet cannot be brought in at every point, the task of ensuring that departmental activities are fitted together in a coherent national effort has tended either to be neglected or to be left to committees—ministerial or interdepartmental. These have not, in the Select Committee's opinion, proved to be fully effective either in decision or in unification, and the maintenance of separate departmental responsibility has operated against unification. At the same time, the report proceeds, the tasks now assumed by Government departments are of a scope which makes it important that there should be some effective independent supervision of their execution, while their nature tends more and more to put upon Government officials tasks which should be handled with the aim of achieving constructive results rather

than merely of adhering correctly to regulations. Risks must be taken, and it is inevitable that mistakes will occasionally be made.

In regard to this aspect, too, there is no unified ministerial authority clearly charged with, and adequately staffed for, the function of reviewing the execution of Government policy as a whole. As regards Parliamentary supervision, the only properly equipped organ of Parliament exercising a function of this kind has a limited field of inquiry. The question of how to ensure the protection of the public interest in the matter of public expenditure, without adopting measures which must act as a deterrent to boldness and initiative, is one which increasingly needs attention.

The Select Committee does not outline a full plan to deal with these matters, as that would involve going far outside its terms of reference. But while it reaches the conclusion that the instruments of financial control hitherto provided by the functions of the Treasury do not meet the need for watching all the reactions of the methods employed for controlling expenditure, or for seeing that the activities of departments fit in with each other as well as with the total economic effort, it considers that the Treasury should be the authority competent to appreciate the Government position as a whole and to satisfy Parliament that the position is being kept under review. The ultimate supra-departmental authority must, of course, be the Cabinet; but the Cabinet cannot exercise the required continuous supervision and needs some instrument with which to work. The Committee suggests that for some purposes the role of the Treasury should be more widely interpreted and more constructively exercised, but beyond suggesting the appointment to the permanent Treasury staff of one or two highly qualified men to be kept free from other departmental duties, and the setting up of an advisory panel of men with practical experience in production methods and cost-accounting, including independent chartered accountants, it deliberately refrains from specifying any detailed arrangements.

These conclusions may well be compared with those reached by Political and Economic Planning in regard to the organization of foreign publicity, another field which presents some complicated departmental relations. The policy which has to be interpreted abroad may be made in a number of different departments. Vital questions to be asked in determining the form which the organization of foreign publicity should take are whether each Government department should look after its own overseas information service, and whether we should reproduce in peace-time the distinction between the British Council and whatever body discharges the relevant functions of the present Ministry of Information. Surveying the position next from the consumer end, the broadsheet takes the view, contrary to that expressed by Mr. Law in the debate in the House of Commons on the proposals for Foreign Service reform, that the number and range of specialist officials will increase, particularly in the economic field, and visualizes nutrition, agricultural and labour experts attached to the Embassy staffs, possibly with attachés concerned with the Colonies and colonial policy. In this context PEP suggests that the official concerned with information, publicity and the Press, the public relations secretary or counsellor, while directly responsible to the ambassador or minister, must look homewards through the ambassador but for a co-ordinated and coherent public relations policy and for the supply of creative material. In this matter the initiative must often come from home, however much we may stress the importance of the public relations secretary, and indeed all overseas personnel, being of the highest calibre.

Without going into further detail, it must be emphasized that news is fundamental to Government information and publicity work abroad and that it may not in practice be easy to draw a dividing line between the cultural field and political publicity. Political and Economic Planning favours the attempt to do so, entrusting the former, including the popularization of British achievement in science, medicine and agricultural and industrial technology, to the British Council, and it advances powerful arguments in favour of re-creating the Foreign Publicity Department of the Foreign Office.

In advocating that political publicity in the widest sense should be under the control of a revived Foreign Publicity Department of the Foreign Office, staffed at its higher levels by permanent members of the Foreign Service, with a good deal of autonomy, a high status, and the right to be heard before foreign policy is formulated, Political and Economic Planning makes clear the aims which such publicity should serve. After the War, that aim should be the full and fair exposition and explanation of the policy, background and cultural life of a country to the public opinion of others. Pressure propaganda and concealed methods of any kind must be strictly avoided. So conducted, Government publicity services should be a force making for better understanding and for peace, and the broadsheet also visualizes an International Information Office, the functions of which would include publicity for international political and economic agencies.

There is much in this broadsheet which is highly relevant to the discussions of a publicity service for science which have taken place in recent months, but in the present connexion its bearing on the general problem of the machinery of government is also of interest. On some specific points, recommendations for the co-ordination of departments follow suggestions which have appeared in reports of the Select Committee on National Expenditure; but on the broad issue, the line of approach adopted is that which must be applied to larger questions, as well as to particular problems such as that of publicity. Only as the functions required and the problems they present are submitted to fundamental analysis from both the consumer end and the production end can we hope to arrive at a scheme which will provide the service demanded to-day of a central government, without placing intolerable and impossible strain on those individuals from the Cabinet downwards who are required to operate the machinery devised.

The analysis of particular problems in this way enables the principles to be laid down in handling the broader and more general problem to be determined with some assurance and precision. As might be expected, this is the approach adopted by Political and Economic Planning in a subsequent broadsheet in which are formulated its proposals for a Civil general staff. In the sphere of government, we have failed to take account of the enormous development in control over material environment, particularly over communications which has characterized this century and so greatly complicated the task.

Unfortunately, a tendency for discussion on war-time controls and their retention or dispensation after the War to pass into the sphere of faction has somewhat obscured this necessity for looking into the fitness of the machinery of government for its tasks and dealing with what may be called the problem of obsolescence. Similarly, faction obscures the fact that the true safeguard against the power of an efficient administration is not a less efficient machinery of executive government, but a strong and representative House of Commons, more of the members of which are in closer touch with, and understand more clearly, the processes of administration. The one inescapable condition placed on any policy-planning organization in a democracy is that it must be purely advisory to those representatives of the people who will have to take the executive decisions.

The recent proposal of Lord Chatfield for a defence council is a particular example of the planning suggested by Political and Economic Planning to remedy the inadequacy of the pre-war machinery of government in the field of fact-finding, planning for future policy, and co-ordination and timing of policy. The problem requires tackling both within the departments and at the Cabinet level.

A major problem is to provide for the organization and co-ordination of national policies and their execution at a level intermediate between that of the Cabinet as a whole and the individual minister. The P E P solution of this problem is along the line of a group of ministers with special functions and without departmental responsibilities, and the central planning organization would conform to this pattern. Within each major department it suggests the creation of a planning group, distinct from, but in working liaison with, the various administrative divisions, and directed by a standing policy committee in close touch with the minister. There should be some flexibility according to the methods of exploring particular problems and working out policies, but the departmental planning group should always play its part.

Some inter-departmental problems could be handled by joint action between the departments and their respective planning groups, but for those of major and general importance and for the co-ordination of policies, a central planning organization will be required and should form part of the Cabinet office. As model for this the organization which has been built up for the purposes of civil administration in the War is suggested, and in general the proposals recall the recommendations of the Haldane Report, although the advisory bodies to which that report attached some importance no longer find favour. On the importance of adequate provision for the continuous acquisition of knowledge and the prosecution of research to furnish a proper basis for policy, of unimpaired ministerial responsibility and of effective Parliamentary control there is close agreement. The core of the problem really lies in those issues which cut so completely across departmental boundaries that no single department can be said to have a predominant interest.

Recognizing that the Cabinet of the pre-war pattern was far too large to be an effective instrument for shaping major issues of national policy, the broadsheet contemplates a pattern in which the Cabinet, which might be somewhat larger, is organized into two differentiated groups: first, the departmental ministers as at present and, secondly, a much smaller group of ministers without any direct responsibility for departmental administration, but directly or concurrently responsible to the House of Commons for planning in some particular field and for taking action to secure co-ordination between the departments concerned. Normally these members would form a planning committee of the Cabinet, and the broadsheet visualizes these co-ordinating ministers in the first phase after hostilities cease as organized in five groups: external relations, defence, social developments and welfare, national resources (including land) and production and distribution, which at least conform to the principle laid down by the Haldane Committee that the business of government should be distributed according to the class of service rendered.

In regard to the central planning organization, the broadsheet suggests that the present Cabinet secretariat, the Economic Section, which at present operates primarily as the staff of the Lord President's Committee of the Cabinet, and the Central Statistical Office, strengthened possibly to meet the requirements outlined in the recent memorandum by the Royal Statistical Society, would at least in broad outline satisfy the requirements of peace-time policy-planning at the centre. It stresses further, however, the value of a working liaison between the departments and universities and research institutions, and due flexibility in the use of appropriate agencies outside government in dealing with particular problems. At this point, however, we find once more that stress is laid upon the vital importance of selecting planning staff, both in the departments and in the Cabinet office, with the requisite aptitudes and techniques.

Directing attention to the temptation to self-sufficiency to which a competent Civil Service is exposed, the broadsheet stresses the dangers which follow, particularly in the scientific field. Departments are slow to mobilize in the public interest the discoveries and achievements of modern science, and unwilling to give scientific men a full share in the constructive work of government. Civil servants likewise know far too little of the relevant experience of other countries, and the broadsheet for such reasons urges that the planning group should be empowered to use freely agencies outside the Government, such

as the universities, research institutes and individuals for particular pieces of work. Such institutions and individual experts are usually free from the inhibitions which often restrict the outlook of the departments, and also command sources of information of current developments in research and ideas which are lacking in the more traditionally minded departments.

There is undoubtedly room for more interchange, in both directions, of personnel and information between the State departments and universities and similar institutions. Specialists might well be employed temporarily for particular studies, but the planning staffs should include particularly men with qualifications in, and up-to-date knowledge of, developments in the natural and social sciences, with a large proportion of temporary appointments of experts. Flexibility of mind and flexibility of personnel in the planning group are as essential as flexibility of organization, and the training to be given to the selected personnel must be not so much in the practices of the past as in the problems of the future and of the methods of attacking them.

The broadsheet reveals no disregard of the experience of the past. It draws on the concept of Combined Operations, and the suggestion that experience gained in the War may help us here in planning for peace should not be dismissed without examination. A planning staff is visualized as consisting of Civil servants carefully selected without prejudice to their future career, a few picked people from universities and research bodies on limited engagement, and specialists in a working or consultative capacity and not necessarily whole-time. Transfer of individuals from one group to another and between departmental planning groups and the Cabinet Office should be encouraged, and a working liaison between the departments and the universities and research institutions is important to facilitate this interchange of staff and particularly its disposal when any particular task is completed, whether of a group or of an individual.

That there are many difficulties in developing any such arrangements is not disguised in the broadsheet. The advantages inherent in such flexible systems are too well attested to warrant hesitation in applying them to the attack on post-war problems. What is required in the first instance is clear thinking on the functional division of ministerial responsibilities, the resolute application of an adequate policy of reorganization, and the creation of the appropriate planning organization with the proper arrangements for staffing. That must be the first step, and then only can we proceed to the recruitment of staff with the requisite aptitudes, on the quality of whom the successful functioning of our machinery of government will depend in the future as in the past. But no excellence on the part of the Civil Service, whether permanent or specially recruited for particular planning tasks, will ensure results unless the machinery is functionally and administratively sound, and stimulates initiative and vision; giving full play to the knowledge and ability and creative powers of those who use it, while retaining unimpaired the essential responsibility to Parliament.

DEDUCTIVE GENETICS

Genes and the Man

By Prof. Bentley Glass. (Science in Modern Living Series.) Pp. xii+386. (New York: Teachers College, Columbia University, 1943.) 3.50 dollars.

PROF. GLASS'S book is intended for teachers, and might form the text for a course of lectures on biology, particularly in its application to man. Its structure is definitely original. He begins with an account of the cell, including the organization of the nucleus as revealed by genetic studies, describes the segregation of genes and their functions in development, culminating in an account of human development which allows him to describe a good deal of elementary anatomy and physiology.

The notion of a gene is introduced on p. 9, and biological facts are described, so far as possible, in terms of genes. He dispenses with any serious attempt to prove the existence of genes, which are, after all, hypothetical, like atoms or electrons, from the consideration of large-scale phenomena. Yet a teacher should surely be encouraged to state the evidence for such hypotheses as genes, atoms, or radiative waves with the utmost clarity if his pupils are to understand the nature of scientific method.

However, a deductive exposition of genetics might be of great interest if it were as accurate and logically coherent as that of dynamics as usually taught. Unfortunately, Prof. Glass's exposition does not possess these virtues. He devotes no less than thirty pages to an account of mitosis, but the exposition of meiosis given, for example, in the diagram on p. 66, is incorrect, save for a few exceptional organisms such as the male Drosophila. True, the account is corrected on p. 120, but meanwhile the reader will have learned that the first meiotic division is always reductional. This is simply untrue for most genes in most organisms; and until this fact is realized much of modern genetics is utterly unintelligible. So is the mechanism of meiosis, for chiasmata have the double function of holding the bivalents together at first meiotic metaphase and allowing the interchange of genes between homologous chromosomes. It is striking that Prof. Glass describes Belar's "Die cytologischen Grundlagen der Vererbung", published in 1928, as "the most complete and best survey yet made of the cytological bases of heredity". The book certainly marked an epoch; but a very great deal has been discovered about the chromosomes since Belar's death.

Unfortunately there are a good many other inaccuracies in the book. Two of my own exploded hypotheses are put forward (fortunately without acknowledgment), namely, that the exceptional linkage in Apotettix is due to translocation, and that structural homology is a product of genic homology, though Nabours has disproved the former, and Harland the latter. We are told that more human genes have been detected in the X-chromosome than in all the rest combined. In his classical "Inherited Abnormalities of the Skin and its Appendages", Cockayne lists thirteen sex-linked genes and ninety-eight autosomal, and the proportion is fairly similar for genes affecting other organs. Blood plasma "contains salts in concentrations strikingly similar to those in sea water"; and so on.

Nor is the logic much more reliable than the facts. We are told that racial prejudice is "biologically absurd", because "it is unlikely that there are many more than six pairs of genes in which the white race

differs characteristically, in the lay sense, from the black". No believer in Negro inferiority should have much difficulty in countering this argument. One pair of genes is quite enough to make a man an idiot, and Keeler and King have produced strong, if not absolutely conclusive, evidence that the differences in tameness, brain size and other characters between wild rats and a tame strain are due to three colour genes. Scientific arguments against the congenital inferiority of Negroes must be based on facts such as those discovered by Davenport and Steggerda, rather than on deductive arguments which are scarcely more cogent than the story of the curse on Ham. Many of the other sociological deductions from biology seem to have an equally flimsy logical structure.

Nevertheless, Prof. Glass's book raises an interesting problem. Would it not be possible to write a text-book of genetics on deductive lines, like a treatise on mathematical physics? The early chapters of Fisher's "Genetical Theory of Natural Selection" represent what would be a section of such a book, and Chapter 7 of Woodger's "The Axiomatic Method in Biology" yet another, though I think that even to-day an axiomatic treatment would be premature. But such a text-book would certainly be mathematical, even if it did not use logistic symbolism. Its main value might be the revelation of gaps both in our knowledge of genetics and in its logical structure. Nevertheless the attempt would be worth making, if only because genetics is the only branch of biology which could be treated in such a way.

Prof. Glass's approach is original, and if the book were rewritten with a careful eye on errors of fact and logic, it would be of great value to teachers of biology. In its present form it contains many useful hints on the exposition of the subject, and in particular shows the central position of genetics; but the reader must be advised to exercise his critical faculty to the full. J. B. S. HALDANE.

COLOUR SENSATION IN MAN

The Fundamental Colour Sensations in Man's Colour Sense

By Gastaf F. Göthlin. (*Kungl. Svenska Vetenskapsakademiens Handlingar*, (3), 20, No. 7, 1–76.) (Stockholm: Almquist and Wiksells Boktryckeri A.-B., 1943.)

RECOGNITION of colour is a process depending upon nerve impulses reaching the cerebral cortex; hence it cannot be overlooked that interpretation of the impulses is a cerebral function. At present it is believed that nerve fibres conduct only one form of impulse and that a different fibre is required for each separate sensory factor. The retina has to initiate nerve impulses corresponding to the pattern of the external world as well as the colours of the various objects. The merit of the trichromatic theory of colour vision is that the numbers of nerve fibres are reduced to three groups, one group for each 'fundamental' colour. The 'fundamental' colour is thus the sensation produced by impulses passing up one group of nerve fibres. The theory is based on the observation that all colours can be reproduced by the combination of three separate regions of the spectrum. The simplest acceptable assumption is that there are three sets of receptors, possibly two varieties of cones and one of rods.

Prof. F. Göthlin, of Uppsala, has published a monograph on some aspects of colour recognition. Section 1 gives an outline of the history of the trichromatic theory of colour vision. As already pointed out, this postulates three 'fundamental' colours, that is, three groups of receptors which are selectively stimulated by different regions of the spectrum. These three groups of receptors must send impulses up three groups of nerve fibres to the cerebrum. Section 2 deals with the problem of yellow. Is the sensation of yellow the result of stimulating one special type of receptor with impulses passing up one group of nerve fibres, or is it the result of stimulating two sets of receptors with impulses up two groups of nerve fibres? There are several peculiarities about that region of the spectrum which gives rise to the sensation of yellow. (*a*) The range of wave-lengths which give rise to a pure yellow sensation is very narrow, and it does not correspond to the same region in all individuals. Göthlin believes that this is conclusive evidence that the sensation of yellow is not a 'fundamental' one, but it might be that the receptors in different individuals do not respond to exactly the same wave-length limits. (*b*) There is a maximum colour discrimination in the yellow region. (*c*) A yellow sensation is produced when a red light shines in one eye and a green in the other. Therefore fusion of red and green to give a yellow sensation must take place either in the external geniculate body or the cerebral cortex. The conclusion is that the sensation of yellow is a delicate balance between impulses which should give rise to red and to green respectively. Psychologically, yellow is a pure sensation, but physiologically it is not a 'fundamental' colour.

Section 3 contains a discussion of the nature of the third 'fundamental' colour, red and green being the other two. Some authorities have selected blue and others violet as the sensation produced by impulses passing up the third group of nerve fibres.

Section 4 describes experiments to test whether blue or violet is the 'fundamental' colour. Prof. Göthlin examined the thresholds for light and for colour in six individuals using indigo (425–465 mμ) as a test light. In three of these individuals the first colour to be recognized throughout the whole region was blue, and the intensity had to be raised further before the colour was called violet. Göthlin argues that the special receptors are those that correspond to a sensation of blue and that the violet sensation is due to a red element conducted up a different set of nerve fibres. He says that he does not know whether the red element is due to stimulation of special receptors adapted to respond to the short wave-length end of the spectrum, but he thinks that the impulses must pass up the same fibres as those which conduct the impulses giving rise to the sensation of red initiated by the long wave-length end of the spectrum. The simplest explanation, surely, is that the receptors for red are stimulated both by the long and short wave-lengths of the visible spectrum. The fact that two subjects saw the dissociation of indigo into blue and violet at some wave-lengths only and one did not see it at all may be due to the difficulty of the experimental procedure.

Section 5 is devoted to a discussion of the nature of the receptors in the human eye. Göthlin considers that the colour filter mechanism, which occurs in birds, reptiles and amphibia, is without significance; yet it is no more improbable than the other explanations suggested.

The curves of colour sensitivity do not necessarily correspond to the ease of stimulation of the receptors by the spectrum. Göthlin states that the possible

mechanisms are: (*a*) separate 'visual substances' with selective light absorption in their respective regions of effectivity; (*b*) a substance of general sensitivity but associated with special sensitizers for the special regions of selective activity; (*c*) a substance of general sensitivity, each receptor being adapted to its effective region by some special physical structure entailing a selective absorption of energy radiations of certain determined wave-lengths. It is not clear whether colour filters are included or excluded from alternative (*c*).

Section 6 presents a working hypothesis. This hypothesis includes the idea that certain stimuli which give rise to one coloured sensation can inhibit impulses which would give rise to the sensation of another colour. This view that inhibition may occur to prevent stimulation of retinal elements from sending impulses to produce their usual colour sensation is not new, as it has been advanced, for example, by the present reviewer[1], and it is the underlying cause of the experiments on 'rivalry'.

Prof. Göthlin presents an interesting mechanical analogy to explain the balancing of the three-colour mechanisms. There are many other interesting points discussed, but these must be found by reading the original monograph. The translation into English is excellent. H. E. ROAF.

PHILOSOPHY OF ECONOMICS

The Ideal Foundations of Economic Thought

Three Essays on the Philosophy of Economics. By Dr. W. Stark. (International Library of Sociology and Social Reconstruction.) Pp. viii+219. (London: Kegan Paul and Co., Ltd., 1943.) 15*s.* net.

DR. STARK, an economist from Czechoslovakia, has included in this volume a series of critical essays in the philosophy of political economy. His attempt to throw familiar strands of doctrine into new perspective gives his work a pleasing quality of freshness. The author's interest is moral and religious as well as economic: he disapproves of the modern tendency to cut away economics from any ethical roots and, resting it on the individual divorced from his social setting, to glorify freedom at the expense of equality. His outlook is one of hostility to the positivistic tendencies of the nineteenth century. Classical political economy of Adam Smith and his successors is considered by Dr. Stark to be superior in this respect to the modern; and he uses what he deems the greater breadth and depth of the former as touchstone to the latter. "The decision between the social and ethical approach of the classical and the individualist and scientific approach of the modern economists," he concludes, "depends upon the question whether it be desirable or even possible to divide the search for the true from the quest for the good." In his view, "the vital link between them should not be severed", since "of all creatures which we know man alone has the privilege, and the duty, to raise his face toward that Infinite Perfection, in whose image he has been formed".

The book falls into three parts. The first, in many ways the most interesting, emphasizes the essential continuity between the views of Locke and of Leibniz, on the contrast between man and Nature and on the relations of man to human society, and the outlook of the classical economists. "The theories set forth by François Quesnay and Adam Smith lie, not only in the economic and social, but also in the philosophic thought of the time that preceded them; and indeed they owed more to Locke and Leibniz than to Monchrétien and Mun". It is implied that neglect of this connexion has been the ground of much subsequent misinterpretation. Dr. Stark indicates, as the key to understanding of these early writers, the fact that the unity between freedom of the individual and the good of society which they postulated rested on the assumption of an economic society of petty production by individual worker-owners. In such a society, economic freedom would include equality of opportunities, and the vesting of property-rights in labour which Locke had expounded would acquire meaning. But the rise of industrial capitalism was to bring this conception into conflict with reality. "The industrial revolution changed the outlook: the trend of development no longer pointed towards a social organization of small-scale production, based on the concord of peasants and artisans; under its influence an economic system of large-scale industry sprang up, carrying with it the discord of possessing and dispossessed".

In the second part, the author examines at some length the views of two representatives of that group of writers who had begun to appreciate that "in and through the industrial revolution the principles of liberty and equality [had become] irreconcilable": namely, Thomas Hodgskin, who criticized the inequality he saw around him but remained "an egalitarian liberal" adhering to a policy of *laisser-faire*, and William Thompson, who looked to a co-operative Utopia to supplant the existant atomistic competition. In the third part, Dr. Stark approaches a more familiar theme: the transition to the modern subjective theory of value, with its concentration on the relation between commodities and the psychology of the individual consumer. As representatives of this modern tendency he takes two less-known writers, Hermann Gossen and Richard Jennings. For Dr. Stark the essence of this transition was the disintegration of the old social philosophy and its replacement by the view that economics was a non-normative positive science; and the very deficiencies of the latter demonstrate that, if equality is to be pursued as an ideal, it can no longer in modern society be "the demand for a just division of the national wealth among all: in a society of proletarians it must be the call for the full concentration of the means of production in the hands of the community".

Dr. Stark writes with an ease and grace of style that is remarkable for one for whom English is not his mother tongue. His handling of ideas and their history shows a rare erudition and discernment. While few readers can fail to find these essays stimulating, there will be few, I think, who will not at some point be provoked to disagree. For the author's canons of criticism are individual and unusual: a quality which gives to his work much of its freshness. He is hostile to the modern tendency to analyse society in terms similar to those employed in the realm of Nature. He is hostile alike to capitalism and to the emphasis of most contemporary economic thought. But his criticism of contemporary ideas and institutions is less from a Marxist than from an idealist point of view; and as regards the method of economic inquiry, it is for a return to its ancient philosophical tradition that he pleads.

M. H. DOBB.

Basic Radio

By C. L. Boltz. (Nelson's Aeroscience Manuals.) Pp. 272. (Edinburgh and London: Thomas Nelson and Sons, Ltd., 1943.) 5*s*. net.

THIS book is one of a series of manuals covering a range of subjects suited to the needs of aeronautical students. It is of the nature of an elementary text-book, illustrated occasionally with descriptions of typical experiments, and provided at the end of each chapter with a series of exercises to test the progress of the reader's knowledge. The scope of the book is more than is indicated by the title, since no prior knowledge of electricity is assumed, and the first half of the manual describes the fundamental properties of electric currents, how these are produced, and the heating, magnetic and chemical effects that result from their use. The notion of electric charge is not utilized until Chapter 6, on condensers, is reached; and following this the nature of alternating currents is described and the manner in which these currents are affected by circuits containing inductance and capacitance. A chapter on waves describes the production of electromagnetic radiation from circuits carrying alternating currents of radio-frequency, and the main phenomena accompanying the transmission of wireless waves are dealt with very briefly. Five chapters in the later portion of the book describe the main facts concerning thermionic valves and the manner in which these are used for the generation of oscillations and for detection and amplification in wireless receivers. Other chapters deal with the use of aerials and feeders, and the methods of modulating the waves for signalling purposes.

Only the most elementary knowledge of mathematics and physics is assumed, and this can, if desired, be obtained from a perusal of other manuals in the same series. Although the subject-matter is arranged in such a way as to make this volume suitable for use as a class text-book, it will be found to be quite readable by the private student.

Clouds and Weather Phenomena

By C. J. P. Cave. Second edition, revised. Pp. viii+24+42 plates. (Cambridge: At the University Press, 1943.) 5*s*. net.

THIS little book contains a series of forty-two pictures of clouds, all beautiful examples of the photographer's art, and excellently reproduced, covering the common types of cloud. The letterpress of twenty-two pages begins with an account of the classification of clouds, including a brief but clear description of each type of cloud. There follows a discussion of the colour of the sky, sunset rays, the green ray, rainbows, haloes, coronæ, iridescent clouds, brocken spectres and mirages. The book contains a considerable amount of information of a character which is seldom to be found in books which aim at popularizing the study of meteorology, or even in more pretentious books.

The author has aimed at providing for those who depict or watch the sky, a simple account of the colours and other phenomena which they see in the sky. He has achieved his aim in a marked degree, and has packed into the few pages of letterpress much information which cannot fail to appeal to anyone who is interested in watching the sky. The book contains nothing too technical for any intelligent reader, and is one of the most satisfying books which have appeared in the field of meteorology for many years.

D. BRUNT.

Post-Graduate Lectures

Inorganic Chemistry, by Prof. H. J. Emeléus; and Organic Chemistry, by Dr. H. B. Watson. Pp. 84. (London: Oil and Colour Chemists' Association, 1943.) 10*s*.

THIS slender volume contains lectures on some interesting aspects of inorganic and organic chemistry which should be useful to those who have not kept abreast of modern work and wish to know something of its teachings. The topics are well chosen and are expounded in a clear and authoritative manner. Prof. Emeléus deals with the structure of inorganic compounds as determined by various methods, such as X-rays and electron diffraction, with crystals, silicates, radioactivity, the separation and applications of isotopes, reactions in gases and in non-aqueous solvents, and cognate subjects. The subject-matter is illustrated by clear and instructive diagrams, and many tables of useful numerical data are given.

Dr. Watson is concerned with showing how modern views on the electronic structure of atoms and molecules throw light on large groups of organic reactions; substitution, addition and isomeric change being chosen as typical. He gives references to original papers for those desiring more information. It is shown how many facts long known to organic chemists find a very lucid explanation when interpreted in the light of one or two quite simple assumptions, and thus organic chemistry is linked with general progress in theoretical physics.

Both sets of lectures are interesting, and a good deal of ground is covered in a way which should attract any reader wishing to learn something of the subjects with which they deal.

Testing Radio Sets

By J. H. Reyner. Fourth and revised edition. Pp. viii+215+10 plates. (London: Chapman and Hall, Ltd., 1943.) 15*s*. net.

THOSE who have to use radio receiving sets, whether for the reception of broadcasting or communication signals, or as an auxiliary piece of equipment in various forms of radio-frequency measurements, are likely to require for occasional reference a book dealing with radio-receiver testing and fault-finding. The present book covers the technique of this subject in a clear and simple manner, and will be found to be a useful elementary manual for the constructor as well as to the serviceman and laboratory worker. The book was first published in 1930, and the present fourth edition has received considerable revision and rearrangement in order to make it as up to date as possible under existing conditions.

Electricity and Radio Transmission

By Sir John Townsend. Pp. xi+183. (Winchester: Warren and Son, Ltd., 1943.) 8*s*. 6*d*. net.

THIS volume comprises an elementary and lucid account of the main facts of electrostatics, magnetism and current electricity, leading thence by way of electromagnetic induction to oscillatory circuits and valve amplifiers and oscillators. An understanding of all this basic knowledge is necessary to a student who is taking an interest in the science of radio-communication, although much the same ground is covered by other elementary text-books. The author's object in presenting this book is, however, to demonstrate in a non-mathematical manner the relation of the principles of radio technique to other electrical phenomena.

SCIENCE AND TECHNOLOGY IN THE NORTH-WEST OF CHINA

By Dr. JOSEPH NEEDHAM, F.R.S.
British Council Cultural Scientific Mission in China

THE previous five articles in this series[1–5], designed to acquaint the scientific workers and technologists of the English-speaking world with the present war-time work and conditions of their Chinese colleagues, dealt first with south-west China (Yunnan Province) and then with western China (Szechuan Province). We have now to report on China's great and undeveloped north-west (the provinces of Shensi* and Kansu).

A brief geographical introduction is necessary at the outset. Leaving the great Szechuan plain (Richtofen's *Rotenbecken*), itself an intermediate plateau between the high Tibetan plateaux and the low-lying plains of China east of Ichang, the traveller enters mountainous country in north Szechuan and south Shensi. Much of this is very historic ground, since it was at these passes that the warriors of the "Three Kingdoms" period attempted to maintain the independence of Szechuan. On entering Kansu province, the road goes for many hundred kilometres through the loess country, which travellers have so often described. The loess is nothing but wind-blown dust from the Gobi Desert of Mongolia to the north, but it covers and cloaks all the geological formations of the region, sometimes to a depth of hundreds of feet; and owing to its fertility and suitability for making cave dwellings, is generally thought to have provided one of the earliest homes of the Chinese people. To the north-west, the province narrows into a 'panhandle', following the line of the Silk Road of antiquity, between the snow-covered Nan Shan Mountains to the south-west which guard Tibet, and the vast wastes of the Gobi Desert to the north-east. Eventually the panhandle broadens out somewhat to meet Sinkiang (Chinese Turkestan), and here it is bordered on the south by the northern Sinised Mongolian province of Ninghsia.

The city of Lanchow itself, about which much must be said, lies on the Yellow River, at the entrance to the panhandle. Here the loess region changes to semi-desert, and the Lanchow area itself is really the first of a series of oases which runs up the panhandle and made the Old Silk Road possible; Liangchow, Ganchow, Suchow, Anhsi (formerly Guachow, the city of melons), and Tunhuang (formerly Shachow, the city of the sands). Some of these were visited by Marco Polo, at his entrance into China by the southern loop of the Silk Road (that is, round the south of the Tarim basin in Sinkiang), and he must have passed, too, through the great Han Dynasty "Gate" of China at Yümenkuan. The later Ming Dynasty one, farther in, at Djiayukuan, is still in excellent repair. Coming down into China, the modern version of the Silk Road, suitable for motor transport (and indeed from 1937 until 1940 the main channel through which assistance, from the Soviet Union, reached China in her struggle against Japan), runs into Lanchow, and then down through Shensi to Szechuan and the cities of Chêngtu and Chungking, with a loop to the city of Sian, and railhead at Baochi. This road, though in general well engineered, is subject to severe disorganization because of the nature of the country. Like the earlier main roads in the western parts of the United States, washouts are frequent and the surface is often inadequately protected against run-off water, presumably because of the lack of labour for road work. The loess country, in particular, is under constant violent erosion, and I shall never forget a day in the rainy season in southern Kansu, when the mountains seemed to be visibly dissolving, and the road was broken by a torrent of dilute brown creamy mud. The Northwestern Road Administration has done a very fine job already, but far more remains to be done before this country can be said to have been mastered.

The whole subject of transportation and communication in Chinese Central Asia is a romance in itself. On the Old Silk Road and other main arteries south of Lanchow run fleets of lorries for which the Government maintains some efficient repair and overhaul stations. These lorries all use petrol, but it may be questioned whether it would not have been preferable in the first instance to have adopted Diesel engines as a definite policy. The drivers are not as yet, of course, all very well educated; hence some strange mistakes, such as the filling up of accumulators with boiled, rather than distilled, water, presumably owing to the well-known medicinal advantages of the former. Besides the lorries, camel trains are still much employed. They operate in sections of about twenty Bactrian (two-humped) camels each; the leading animal carries the camel-driver with a white triangular flag marking the nature of the caravan, and the last animals carry bells in order to avoid their loss by theft unknown to the camel-driver ahead. A number of dogs accompany the trains to assist in protection against the wolves which at twilight abound in the winter near the Road.

As for communications, radio-telegraphy has proved of great advantage in this wild and desolate country; the remotest oases now possess hand-worked radio-transmitters, and a network of communications has thus been established throughout Central Asia. Telegrams in the Chinese ideographic language are sent according to a code, each character having its own number, and it is a remarkable sight to see the clerks transliterating their messages rarely at a loss for the right character or number, though the latter often reach five figures. The radio network forms an interesting contrast to the methods in use in the Han Dynasty (contemporary with the Romans), the beacon towers of which are met with so frequently by the traveller. Besides each ten-li fort there stand five small square conical towers, about 8 ft. in length and breadth and 10 ft. high; in this way the Han garrisons protecting the road could send to each other elaborate messages about the movements of the unsubdued tribes in the mountains to the south-west or the desert to the north-east. The positions of some of these buildings show that the fort was used as a receiving station and the five towers as transmitting stations.

One must think of Lanchow, then, as a city rather isolated at the entrance of Chinese Central Asia. It is nevertheless much modernized, and with its walls, towers and gates set in a loess valley of grand proportions beside the famous river, presents an imposing appearance. Tibetan lamas or notables and Mongolian herdsmen are to be seen in its streets, side by side with the Chinese Moslems of the province and the officials and soldiers of the Central Government. As a pioneer scientific and technological centre,

* I refer only to South Shensi, the so-called Communist area of North Shensi having been out of my itinerary, though it contains some interesting scientific institutions.

pushed out into Central Asia, it is very significant, not only now but also in its promise of future importance.

Apart from the machine shops of the truck transportation departments of the National Resources Commission and the Northwestern Road Administration, there is a large machine works jointly under the National Resources Commission and the Kansu Provincial Government, directed by Dr. Hsia An-Shin. This turns out lathes, drilling machines, shapers, centrifugal pumps, machine looms, etc., and serves the whole of China's north-west, including Sinkiang. It was interesting to see among their old machinery a 100-H.P. rolling mill for minting the copper 'cash' of former days; it is now intended to use it as a mine hoist. To stand in Dr. Hsia's foundry is to feel on the edge of some vast ocean, for there is nothing else of the kind between Lanchow and the Soviet Union two thousand miles or more to the west. The National Resources Commission also has a successful dry-cell factory and power station at Lanchow; here it was interesting to see, with Mr. Yang Chêng-Ching, insulators of all kinds of telegraphic apparatus entirely Chinese-made. Besides these industrial activities, there are flour mills, woollen mills, and a wool-washing plant, under partial Government control; and a great deal of work going on under Chinese industrial co-operatives. Some thirty branches exist in Lanchow, covering the leather, textiles, fur, paper, machine, brick and tile industries. In other cities such as Baochi, the number of such producing co-operatives may be so high as seventy. It was interesting to see, at Shuangshihpu, the Chinese Industrial Co-operatives Machine Works' pattern-shop set up in an old temple, and the wooden machine parts piled around the dusty Taoist gods. As is well known, the procedure in the Co-operatives is very democratic, and I was introduced to the chairman of the Lanchow co-operative federation, Mr. Wei Yu-Ling, an illiterate, but obviously very intelligent, textile worker, whose organizing ability has won him successive elections to this important post.

Lanchow is as important a medical as an industrial centre. It is the seat of the Northwest Epidemics Prevention Bureau's Vaccine Production Institute, analogous to that at Kunming in Yunnan, mentioned in my second article[2]. The Lanchow Institute is directed by Dr. Yang Yung-Nien, a former student of Sir Henry Dale, who worked at the National Institute for Medical Research with Dr. P. Hartley and Dr. Booth White. Apart from the usual vaccines, of which some 80 per cent go to the army, the Institute also produces diphtheria toxoid, and vaccines against cattle and sheep anthrax, and rinderpest. About eighty ponies are kept, with a special ranch for pasture feeding, and half a dozen large Arab horses captured from the Japanese. Like the Kunming Institute, the Lanchow Institute has its own glass factory. Owing to the extremely dusty nature of the country, work is almost impossible during the summer months, on account of contamination in the absence of up-to-date air-conditioning devices.

In the Pathological Department, the visitor immediately notices piles of mollusc shells on the chief's desk, and it was therefore no surprise to find that Dr. Li P'ei-Ling had been a pupil of Prof. A. E. Boycott. Dr. Li is not working at present, however, on the dextrality and sinistrality of Helicella, but rather on the position of this snail as a vector in the spread of lungworms and flukes in sheep. He is, in fact, an enthusiastic comparative pathologist. Even in this institute, the lack of materials and apparatus was depressing, although as a whole it is well-equipped with stores, considering all the conditions.

Another outstanding worker under the National Health Administration at Lanchow is Dr. Mêng Mu-Ti, one of China's best pharmaceutical chemists, and a former colleague of Prof. J. H. Burn. He is now engaged in starting a Government pharmaceutical factory, and work is proceeding on the making of petroleum jelly from the residues from the oilfield, mentioned below; saponins from soap beans, pure salts and borax from Chinghai (Lake Kokonor) bitterns, potassium permanganate from pyrolusite, ephedrine from *ma huang*, eumenol from *tang kuei*, etc. In this connexion, the following contrast is of interest. Everyone has read of the use of butter by the Tibetan lamas in their monasteries for modelling coloured pictures, burning in shrine lamps, etc. Recently the Chinese Air Force has established a casein factory at the famous lamasery of Labrang (Hsiaho, not very far from Lanchow), so that the butter now goes to a more technical, if less traditional, use. From the whey, lactose is prepared by Dr. Mêng Mu-ti's laboratory workers.

In medical education, Lanchow is also important. The National Health Administration's Personnel Training Institute, presided over by Dr. Li Wên-Ming, produces dispensers, sanitary inspectors and 'nursing assistants'—these latter may be regarded as analogous to the old Russian grade of 'feldshers' in remote country places, who were not medically qualified, but had sufficient medical education to run rural clinics 'of first appeal' and attend to public health. A somewhat superior grade of such men is being turned out experimentally by the Northwestern Junior Medical School, also in Lanchow, under Dr. Chi Ching-Hsing; here medical men are to be trained in four years instead of six, with a 'rural' instead of a regular qualification diploma. The emphasis is on practical rather than theoretical knowledge. It remains to be seen how successful this will be, but the Chinese certainly have an enormous problem in introducing modern medicine into Central Asia, and in the opening stages a system such as this may be very beneficial. Besides the above, Dr. Li Wên-Ming's Institute also organizes refresher courses for medical men, nurses, public health officials, and the groups originally trained there. Dr. Chi has on his staff the brilliant Edinburgh surgeon, Chang Cha-Li, whose work at the National Health Administration's Northwestern Hospital is very noteworthy. It was at this hospital that I noticed a little touch exemplifying the Chinese genius for improvization—on a table outside the clinical laboratory door, an egg-shell was lying; but it had a label attached to it, and on closer inspection proved to contain a pathological specimen. In the shortage of glass tubes, what more suitable sterile container could be found. Lanchow has another excellent hospital and leper colony under Dr. S. Hoyte of the China Inland Mission.

Among the most interesting of Lanchow's institutions is the Kansu Science Education Institute. This organization, a group of Chinese-style buildings in a beautiful garden just outside the city, was started with British Boxer Indemnity Funds in 1936. Successive directors were Profs. J. B. Tayler and Y. P. Mei of Yenching University; the present head is Dr. Yuan Han-Ching, a specialist in stereochemistry from Roger Adams' laboratory at the University of Illinois. It was intended to be a research institute as

well as a focus of Central Asiatic popular education in science, but under present conditions very little research can be undertaken. There is, however, work proceeding on the ecology and entomology of the Nan Shan Mountains, and the institute has a useful library. Particularly active are the workshops, under Mr. Hsieh Yu-Shou, making scientific apparatus for the schools of the province. This resembles that produced near Chêngtu (and referred to in the fourth article of this series[4]); tuning-forks and pulleys are made of salvaged aluminium from shot-down Japanese aeroplanes, and weights for chemical balances from melted bronze coins of former dynasties. About a hundred complete sets of eighty pieces of apparatus each are produced each year. The section of geology and mineralogy, moreover, produces boxed sets of ore and rock specimens, as well as wooden stratigraphic models, which were pronounced by a geological friend who accompanied me as better than those he had seen in many Western universities. Then the popular science education division under Mr. Chêng An-Lun is also active, and some of its work is to be seen in the large illustrated wall-newspaper, changed once every ten days, and set up at the city's civic centre. During my stay in Lanchow, I noted interesting articles on Archimedes and the history of geometry, on twinning and other questions in experimental morphology, and on parasitic insects.

The Chinese Industrial Co-operatives also have a research institute in Lanchow; it has a good library, and carries out work on leather technology, wool textiles, etc.

Coming now to more formal technical and scientific training, though no university exists in Lanchow, there are a number of institutions worth notice, since here in Central Asia, learners are truly in the 'front line' of science and technology. First, there is a Teachers' Training College, the largest of its kind in China, under Dr. Li Chêng, which includes scientific instruction; and then there is a Polytechnic College (similar to that at Chiating described in the fourth of this series of articles[4]) under Dr. Tsêng Chi-Kuan, specializing in animal husbandry, agronomy, irrigation, etc. Of particular interest are the Technical Training Schools of the Chinese Industrial Co-operatives, which exist at Shuangshihpu and Chêngtu, as well as at Lanchow. Here many child workers of promising intelligence are given a good all-round as well as technical education. At Lanchow one can see boys of sixteen or so acquiring an insight into all the mysteries of the textile industry, or a couple of Tibetan-Chinese youths newly arrived from the back country at work on the solid geometry of the screw-thread. The Co-operatives' schools, which act also as centres of local culture, keeping alive such things as the folk-songs of the people, are named Baillie Schools, after Joseph Baillie, an ex-missionary who devoted his life to the cause of technical education in China.

Before leaving the city of Lanchow, a few words may be devoted to some of the American technical experts who have made it for a time their headquarters. Dr. Theodore F. Dykstra, whom we have mentioned before, has been at work on a widely extended survey of potato culture across the length and breadth of Free China. There can be no doubt that his efforts will help greatly in the freeing of the Chinese potato crop from the curse of virus diseases of all kinds with which it has so far been infested. Dr. W. G. Lowdermilk, an internationally known erosion and soil-conservation expert, with a group of Chinese colleagues, such as Dr. Stephen Fêng, has also gone up and down the country, and they will be making important recommendations for the better conservation of the north-west, and the fight against desiccation. In this connexion, mention should be made of Kansu's exceptionally enlightened Commissioner of Reconstruction, Mr. Chang Hsing-I; according to him, Kansu's greatest problems are the more successful location of subterranean water along the Silk Road, and the full exploitation of the oil throughout the province.

Much has been written on the progressive desiccation of north-western China. I have myself observed in far North-west Kansu that the foothills of the Nan Shan, which are described on Sir Aurel Stein's maps of 1905 as "covered with thick brushwood", are now completely desert, with only the thinnest scrub in the dry watercourses. In Northern Suiyuan (another Sinized Mongolian province) the *pailous* (commemorative arches) of not very far-distant date are now buried in sand up to a foot or two of the top. It is not clear, however, that this process could not be stopped by modern methods of afforestation, soil conservation and irrigation carried on over a sufficiently long period by a sufficiently determined Government. The richness of the oases (for example, Gaoṭai, on the Silk Road in Kansu) and the well-deserved fame of the melons of Hami and Tunhuang, suggest that given irrigation, almost anything will grow on the sandy soil. It would seem that the main need for the north-west is the introduction on an enormous scale of modern agricultural methods. For example, on the rolling loess highlands between Tienshui and Lanchow, especially south of Huadjialing, the whole area could be put under fruit-trees, taking advantage of the lower southern slopes. Given then improved transportation facilities and a canning industry to take care of fruit surpluses, the area could become of great importance for the improvement of the national diet. Szechuan, again, perhaps the original home of the orange, suffers to-day from periodic gluts, which, if cold-storage plants and means of making ascorbic acid concentrates were available, could readily abolish vitamin C deficiency in large parts of China.

Animal husbandry, too, has great importance for Chinese Central Asia. The pastoral culture of many of the tribal peoples such as Mongols and Qazaqs was, and is, based on it, but Tibetans and Chinese also have many flocks and herds. Government sheep-improvement ranches are maintained at Minhsien and Yungchang in Kansu. Both the U.S.S.R. and New Zealand, at the request of Dr. Ku Chien-Chi (now scientific adviser to the Sinkiang Government, then of the Kansu agricultural service) have sent sheep to improve local stocks, and artificial insemination is now being undertaken. The 150 New Zealand sheep of various breeds are still, however, undergoing an odyssey; destined in the first place for the Burma Road via Rangoon, that city fell before they arrived, so they were sent to Calcutta instead; then after an ineffectual attempt to get them in through Assam, they were driven up to Lhassa in Tibet, and at present are somewhere on the road between Lhassa and Lanchow.

Besides the vaccine production institute already mentioned, there is another for veterinary sera at Lanchow, directed by Dr. Frank Liu under the Ministry of Agriculture. Since no refrigeration plant is available, the products are stored underground with ice from the Yellow River, which often freezes over in winter.

The reader must now imagine himself transported away up the Silk Road to a location in Central Asia which cannot be named or identified for security reasons, namely, the oilfield which to-day supplies the greater part of the petrol used by the Chinese. On the way, he will have passed for many miles along the Great Wall, and will have observed the triangulation tripods of the Chinese Geological Survey on some of the towers. At the oilfield, men from the Royal School of Mines (of South Kensington) are prominent; such as Dr. Shao I-Chou, who capably seconds Dr. Sun Yu-Chi as manager, and the oil geodesist, Dr. Ong Wên-Po. The field is one of the highest in the world, lying among the largely unexplored ranges of the Chilien Shan, and the issuing oil is probably the coldest, thus giving rise to special difficulties not met with elsewhere. The refinery, under the oil chemist, Dr. Chin Kai-Ying, produces all grades of petrol and light oils, waxes and greases. It seems clear that the field is a good deal larger than had hitherto been believed, and should be a highly important factor in post-war Chinese industrial prosperity. Nor does it stand alone, for seepages of oil occur all down through the Province of Kansu. They have been known to the peasants probably since remote antiquity, and have been used by them for greasing axles of country carts as well as medicinally; they account undoubtedly for mentions of oil by Marco Polo and for the accounts of "weak water" in other ancient and medieval writings.

Finally, the reader will remember that this region is one of the classical areas of the whole world for archæological exploration. The discoveries of Stein, von Lecoq and Hedin were possible largely because the desert climate preserves all sorts of antiquity in the most perfect way. One has only to dig in the rubbish-heap beside some deserted Han fort to find shards of Han basins, cloth belt of the Tang, a rope-end of the Sung, and broken pottery of all periods. So also the painted plaster surfaces of Lamaist stupa-tombs last in the open air surprisingly for centuries. Some fifteen miles south of Tunhuang, on the Kansu-Sinkiang border, lies the historic site of Chienfotung ("Thousand-Buddha Caves"). Here, for a distance of some two miles along the dry river-bed, the metamorphosed gravel cliff is honeycombed with caves, ranging in size from a suitcase to a cathedral and partially protected from the weather by a small, well-irrigated, and charming oasis.

The walls and ceilings of the caves are covered with well-preserved fresco paintings of all periods from early Wei through Sui, Tang, and Sung to Yuan (A.D. 380–1360), mostly of the earlier periods, illustrating the daily life of the people as well as the rites and ceremonies of the various forms of the Buddhist religion. They constitute, indeed, owing to the perishable nature of traditional Chinese architecture which used wood rather than stone, the greatest natural museum of art and archæology which China possesses. In one of these caves it was that Stein discovered long ago the famous hoard of Tibetan, Manichaean, Sogdian, Sanskrit, and Chinese books, much of which is to-day in the British Museum. In the oasis there is now a Tunhuang Research Station under the Ministry of Education; but unfortunately, in war-time, little has been done to preserve the caves, the painted plaster walls and statues in which do show a certain tendency to break away and spoil. It is a remarkable comment on Chinese traditions of scholarship, however, that in the middle of a war such as the present, their Central Press Agency should maintain at the caves a group engaged on a systematic photographic survey of the frescoes. This site will certainly in the future be the scene of further great discoveries of Chinese archæology.

PHOTOGRAPHIC PHOTOMETRY

A SYMPOSIUM on "Microdensitometry and Microsensitometry" was held at the Royal Photographic Society's House in London on January 29. It was attended by members of the Royal Photographic Society and of the Association for Scientific Photography. There were four speakers: Dr. G. B. Harrison of the Research Laboratories of Ilford Limited; Dr. A. Hunter of the Royal Observatory, Greenwich; Mr. A. R. Stokes of the Crystallographic Laboratory, Cambridge; and Mr. D. M. Smith of the British Non-Ferrous Metals Research Association. Dr. H. Baines, vice-president of the Royal Photographic Society, was in the chair.

After formal opening of the proceedings by the chairman, the subject was introduced by Dr. Harrison. He said that his task was to remind the audience of the more important factors which have to be borne in mind in accurate photographic photometry, particularly microphotometry. After pointing out that photographic materials, being sensitive to light, lend themselves to the comparison of light intensities, he said he wished to emphasize the fact that the use of photographic materials for such purposes is not without pitfalls for the unwary. Photographic photometry is based on the assumption that if two exposures are made on two different regions of the same photographic material, and these exposures are equal in all respects, then the densities produced by the two exposures will be equal. By exposure is meant the total amount of light received, which is the illumination multiplied by the time of exposure. It will be recognized that this assumption is only true under certain conditions, and a thorough knowledge of these limiting conditions is necessary to avoid the pitfalls and to pick one's way skilfully between them.

In practice, the magnitude of the test exposure to be measured will not be known, and it is necessary to record on the photographic material a range of exposures so that a curve relating some function of the exposure to the density produced can be drawn. It is in the application of this series of exposures that lies the key to accurate photographic photometry.

Dr. Harrison then reminded the audience of the requirements, which he said must not be regarded as placed in order of importance, because this depends on the conditions of the work in hand. The calibrating exposures should be similar in size, shape and surroundings to the test area. This arose because the density developed in any given area of material may be influenced by the density being developed in an adjacent area. The fact that the sensitivity varies with wave-length of radiation is so well known that it is obvious that the calibrating source should have the same spectral emission as the test source. Although the photographic material records the total amount of light, it is not indifferent to the way in which it is received. A high intensity for a short time does not give the same density as a low intensity for a long

time, even though the total light received be the same. An exposure broken up into several shorter exposures may not give the same density as a continuous exposure of the same total light value. It is therefore necessary to ensure that the calibrating exposures have the same distribution in time as the test exposures, the intensity only being varied. The test and calibrating exposures should be separated by as short an interval of time as convenient, and if the interval has to be appreciable, a relatively long time should lapse before development. This precaution is occasioned by the possibility of changes in latent image after exposure and before development.

Having thus applied the calibration exposures, it is necessary to secure as uniform development as possible, and to measure all densities on the same densitometer. The particular type of densitometer used is of little importance provided it is capable of giving reproducible results.

Dr. Harrison said he had laid down briefly certain ideals to aim at, and he fully realized that it seemed a discouraging prospect, particularly as the practical conditions of the work frequently preclude the possibility of satisfying all the points enumerated. It is in these circumstances, however, that a full knowledge of the limitations of the photographic process is so valuable in enabling the user to judge, or better still determine, the penalty he will have to pay, if any, for neglecting any of the fundamental requirements. In fact, the art of photographic photometry may be said to lie, not so much in the ability to satisfy all requirements, as in the ability to minimize the consequences of the inability to satisfy all.

Dr. Hunter then followed with an interesting paper on the use of microphotometry in astronomy. He said that photography is probably the astronomer's best friend because it is capable of recording total light and can integrate that light over long periods of time, and because it provides a permanent record. It is surprising how much useful information is obtained as a result of a re-examination of old plates in the light of new discoveries. The main use of photographic photometry is in the measurement of stellar magnitudes, and in the recording and measurement of stellar spectra. The latter give valuable information on temperature, and the Stark and Doppler effects yield data on mass and velocity respectively. The wave-length range concerned usually lies between 3,000 and 10,000A., though astronomers are generally rather suspicious of the behaviour of photographic materials at very long wave-lengths. To give some idea of the light intensities involved, he said that a first magnitude star provides an illumination of about one millionth of a metre-candle, and although the telescope might increase this by about a thousand-fold, it is still a very low level of illumination. When spectra are being recorded, it is, of course, lower still.

Referring to the requirements enumerated by Dr. Harrison, he said that frequently they cannot all be satisfied. For example, if the star image be formed on the slit of a spectrograph, the varying refraction of the atmosphere causes the image to move about, and in any event since the image is necessarily small, it is often artificially moved up and down the slit during the exposure to increase the effective height of the recorded spectrum. The exposure is therefore intermittent, though the calibrating exposure is normally continuous.

Perhaps a more flagrant breach of the conditions occurs when the calibrating exposure time differs from the test exposure time. Exposures are sometimes necessarily lengthy, and it is inconvenient to make the calibrating exposures of the same length. It is recognized that this procedure may lead to errors, and Dr. Hunter recalled an investigation he had made to determine the magnitude of the effect in relation to a series of experiments he was making. The calibrating exposures were made with an exposure time of 20 sec. and the test exposures varied from 20 sec. to more than 500 sec. The error was found to be appreciable and to vary with the type of plate used. He was able to obtain a relationship between observed and true stellar magnitude, so that a correction could be applied according to the test exposure time.

Dr. Hunter then discussed the question of the microdensitometer. He pointed out that most instruments give a record of the variation of transmission against position on the plate. What is really required is the curve of density against position, which can only be obtained by laboriously going over the transmission curve, taking the logarithm of the reciprocal of the transmission, and replotting. He showed diagrammatically the principle of a recording microdensitometer developed in Holland just before the War, which consisted in an addition to be fitted to any existing densitometer. The Dutch succeeded with this instrument in making a new atlas of the sun's spectrum which is already yielding valuable results. The chief drawback to this instrument is that a template has to be placed in part of the optical system of the subsidiary unit, and the shape of the template depends on the characteristics of the photographic material at the wave-length being measured.

In the United States a much more elaborate instrument has been built which overcomes this difficulty. The test spectrum and calibrating plate are both placed in position on the table of the instrument and the preparation of the density record is fully automatic. The instrument is said to be accurate, and a slide was shown of duplicate traces showing extremely good reproducibility.

The meeting was next addressed by Mr. Stokes, who commenced by briefly describing the fundamentals of X-ray crystallography with special reference to the Debye-Scherrer method. The specimen, consisting of a single (rocking) crystal or a 'powder', is placed at the centre of a circular camera carrying a strip of film located on the circumference of a circle with the specimen at the centre. A narrow pencil of X-rays as nearly monochromatic as possible is incident on the specimen, and the emergent beam is trapped to avoid scattered radiation in the camera. The lines in the spectrum are reflected at different angles depending on the lattice structure of the crystal material and the wave-length of the incident radiation. The wave-length range with which the crystallographer is concerned is 0·5–2·5A. The width of the lines obtained depends on several factors, among which is the perfection of the crystal lattice itself. The line width is usually of the order 0·5 mm. on the film.

With reference to the requirements laid down by Dr. Harrison, Mr. Stokes said that the crystallographer is probably in a privileged position in that the photographic material does not exhibit reciprocity failure when exposed to X-rays. It is therefore possible to make the calibrating exposures by means of a time scale, for which a sector wheel giving exposures increasing in arithmetical progression is

used. From density measurements on these regions a curve relating density to exposure can be drawn. This usually yields a straight line up to a density of about 1·5.

Mr. Stokes raised the important question of the effect of the size of the slit of the microdensitometer. The error introduced can be corrected by formula. In this connexion figures were given for the variation of observed density due to the graininess of the photographic material. The variations are appreciable, and it was pointed out that the height of the densitometer slit is limited by the fact that the spectral lines are curved, particularly at large angles of reflexion.

Another interesting point concerns the difference between the appearance of the X-ray spectrum and the recorded trace. A slide was shown illustrating a series of spectral lines and the corresponding density trace. The appearance of one of the lines suggested that there were two lines close together, one being much denser than the other. The densitometer trace revealed that the less dense 'line' was no more than a barely significant shoulder on the record of the line. The second peak was, in fact, not a peak at all, but merely an indication of the existence of a point of inflexion in the density trace. The slide showed the method of taking account of the fog or background which is nearly always present and usually increases towards the position of zero deflexion of the incident beam. It is usually possible on the density trace to draw a smooth line passing through the minimum density positions.

The use of photographic photometry in quantitative spectrum analysis was dealt with by Mr. Smith. The spark spectra of metals or alloys containing small quantities of impurities are recorded photographically, the most important region being in the ultraviolet from about 2,300A. to 4,500A. Spectrum analysis is most useful when the impurities are present in amounts less than about 2 per cent. The principle of the method is that the intensity of an impurity line is related to the intensity of a basis metal line according to the percentage impurity present. The procedure is to prepare a series of standards containing known quantities of impurity, and, by comparing the relative densities of basis metal and impurity lines, to determine the percentage corresponding with the relative densities obtained from the test sample.

Accurate calibration of the plate presents difficulties peculiar to the problem. Since a light source similar in constitution to the test source is required, a spark source is indicated; but unfortunately this is variable in both intensity and in the relative intensities of the different lines. The simplest and probably the most accurate method is to photograph a range of standards samples on each plate; but this has the disadvantage that it leaves less room for test exposures, it rapidly consumes carefully prepared and analysed standards and it appreciably increases the time taken. Another method is to use a rotating stepped sector in front of the slit. This method yields an intermittent calibrating exposure, but it has been claimed that this is permissible provided the sector disk is rotated at a rate of 200–300 r.p.m. The intermittency effect can be overcome by using a stepped density wedge in place of the sector shutter, but this has been little used owing to the difficulty of obtaining satisfactory densities which are neutral over the requisite wave-length range.

Mr. Smith believes that the chief sources of error lie in the inconsistency of the light source, and that errors in the photographic process play a relatively unimportant part. He hopes that the reproducibility of the source will be improved in the near future.

Some discussion took place after the papers in which questions of detail were asked. Mr. L. V. Chilton agreed that photographic photometry has its difficulties and that a complete understanding of the principles involved is essential to success. On the other hand, microphotometry has its own particular difficulties, and though some of the speakers had indeed dealt with certain aspects, there are many interesting points peculiar to this field which could profitably be discussed in detail.

THE FOREST AS A FACTORY

By Prof. E. P. STEBBING
University of Edinburgh

IN a memorandum written for a Government conference last summer, I made the statement that the forest is a "factory" just as much as a factory turning out tanks or aeroplanes. The statement appeared to create some surprise. Let us consider how it may be justified though, with the exception of India, inadequately recognized in that great organization the British Empire and Commonwealth of Nations.

We will first look at India; in spite of the fact that many heads of the other forest services hold that Indian forestry conditions, with all their great range of climate, soils, species, plains and mountains, are not applicable to conditions outside that country. During the War of 1914–18, India very soon found herself, owing to deficient shipping, deprived of many imported goods and left to her own resources. The forests, with an adequate forest staff for the purpose, were soon called upon to supply large military and civil requirements; and the young Forest Research Institute played a remarkable part in assisting in this matter. This is familiar history. Once again, in the present War, the same position has had to be faced in India on an even larger scale. Once again her forests, having been under a conservative management for just eighty years, under an adequate forest staff and assisted by one of the biggest and best equipped forest research institutes in the world, have proved adequate to the call upon their resources.

An examination of some of the War publications from the latter, *Records*, *Bulletins* and *Leaflets*, prove, if proof be necessary, that the forest is merely a giant factory which in combination with the work of the research officer (for example, in an aircraft factory where the combination is now fully recognized) can face new demands, provided a sufficiency of labour is available. Examples of this work have already been given in these columns (NATURE, **153**, 201; 1944). They furnish evidence of how research, with the forest to provide the necessary raw materials, was able to come to the assistance of the Fighting Services, as well as civilians, when imports of many kinds ceased. The research part of the 'factory' solved the problem of finding a substitute article for the one which could no longer be imported; the 'forest factory', according to location of supplies, well known to an organized department, provides the raw material; and the third 'factory' in the business, the only one recognized by so many, makes up the article. But the third would have been non-existent

had not the second existed. A prerequisite to all this organization and its successful issue, without over-exploiting or devastating the national forests, the ownership of which is—or should be—vested in the peoples of the country, depends upon an adequate forest staff, and a working knowledge by the latter of the whole of the forest areas of the country concerned.

A study of recent annual reports of some of the Colonial Forest Services is by no means so reassuring. In many instances the 'forest factory' is being heavily exploited for war requirements without the requisite safeguards, which are adequate knowledge of the contents of the forests and a sufficient staff to superintend excessive fellings. The capital of the country, which belongs to the people of the country, is consequently being dissipated.

Reference has already been made to the heavy unsupervised fellings being made in the United States in the Douglas fir and companion species, West Coast hemlock, Sitka spruce and Western cedar forests to supply war-time demands (NATURE, 152, 651; 1943). Another instance of the same is quoted from Alaska. In the rain-drenched Tongass National Forest of the unknown south-eastern Alaskan panhandle, a forest larger than the State of Western Virginia, is situated what is said to be the world's last great reserve of Sitka spruce, the pre-eminent aircraft timber. Many thousands of these great trees, with a height of 200 ft., 80 ft. clean bole to first branch and 6 ft. diameter at breast height, were felled in 1943; the War Production Board, with much of the best forests in Oregon, Washington and British Columbia cut over, having arranged to open out the Alaskan wilderness.

Many examples from recent publications could be culled to show the position the forest occupies in a country in periods of stress when that country can no longer rely on imports of certain staple commodities. The forest at once forms one side of the 'factory'. Without the forest several types of factory, including one of the latest, the plywood factory, would not exist. No commercial man would consider it possible to run a factory in peace- or war-time without the necessary trained supervisory staff to ensure efficient output and a continuity in that output. Any attempts to reduce such staff as redundant would be met with suspicion and a *non possumus*. Further, it would be equally recognized that to ensure that a continuity of output is maintained supplies of the necessary raw materials must be available in the amounts already calculated.

How does the 'forest factory' come off in this respect? A study of even the few instances given above serves to show that the position of the forest as regards the supplies it affords to the factory dependent upon it and its relation to that factory is rarely understood. The idea appears to be still held in some quarters that the forest can go on supplying indefinitely the products required from it with a very inadequate supervisory staff, if indeed any such staff is present; whereas the truth is that this type of utilization of the forest results (far quicker in war-time) in its gradual exhaustion, and with the latter the collapse of industries and their man-power dependent upon them. For a forest is a delicate organism and easily ruined by ill-judged fellings.

How is the forest to be maintained and safeguarded? To rehabilitate a forest which has been wastefully and ignorantly exploited, in the absence of expert supervision controlling the work, will take a century or more, if timber is the desideratum. How is a continuity of material from the forest and the consequent continuity of the factories dependent upon it to be maintained? A trained and expert staff is necessary for the factory. Equally so for the forest. If, as so often in the past in the British Empire, such a staff is only brought in in inadequate numbers, after the forests in question have been partially or totally ruined by over-exploitation in one or other of its many possible forms, a long and uphill struggle has to be faced and considerable expense. Trees are not agricultural crops; they require considerable periods of time to produce what is required; even if only of small size such as pitwood, fuel plantations and so forth. In the absence of a trained staff, an ignorantly exploited forest, if of conifers, may result in the total disappearance of the forest from the area; if of hardwoods, the same may take place, the time elapsing being much longer. But the final results in many cases may be the disappearance of the population which lived in that neighbourhood. History has already witnessed whole populations moving to more salubrious parts or gradually dying out owing to the destruction of the neighbouring forests, with the consequent impoverishment of the soils and the diminution of the water supplies. In former times the aftermath of forest destruction and impoverishment of the soils only made its appearance over long periods of time; not so nowadays. With increased populations, with increased methods of rapidly exploiting rich forest areas, and greatly improved methods of transport, a forest can be destroyed, so far as its future usefulness to man is concerned, in a comparatively short time, even in days of peace.

In times of war and stress, an accessible forest and, with expense no object, previously so-termed inaccessible forests, unless under the watchful supervision of their only possible guardians, the trained forest officers, fully acquainted with their regions and in sufficient numbers to enforce correct methods of working, can be exploited and ruined in a very short space, as in the American examples quoted above.

In connexion with the improvident and ignorant utilization of the forest by the populations inhabiting the regions in the past, alluded to above, the present-day consideration being paid to soil conservation schemes both in parts of the Old World and the New merits mention here. Perhaps the most modern examples of the ignorant treatment of forest and agricultural soils is to be seen in the popularly termed 'desert bowls' in the United States and parts of Canada; and also in Australia. As a result, thousands of farmer families have had to emigrate, the once fertile regions having been reduced to desert conditions. But the world has had for long many older examples, and over wider regions, of this misuse of the land and its vegetation. The British Empire affords many illustrations, of which large stretches in Africa offer examples. This position is at length being considered from the only possible practical aspect, to wit, soil conservation schemes—schemes the primary objective of which is to stay the further desiccation and spread of desert conditions, coupled, as they invariably have been, with lessening rainfall and water supplies and the migration of the peoples affected.

Excellent examples of the modern changed attitude to this question are afforded by the Governments of the Sudan and Kenya. These Governments have apparently realized that soil conservation must be

approached by bold schemes, not by small experiments of merely local interest having little reference to the broad requirements of the country affected as a whole. In the Sudan, an active soil conservation policy is under consideration. The sitting committee has adopted, it is understood, a comprehensive programme for which a considerable sum has been earmarked, and which, if and when put into force, will immediately provide employment for a portion of the demobilized native troops. In Kenya, projects of development are foreshadowed. The principal scheme is one for soil conservation, for which it is said a sum of £940,185 has been allocated.

The forester will indubitably take an active part in this work; for trained supervision will be essential if money is not to be wasted. One of the forester's jobs will be an endeavour to replace blocks of forest on the ruined and impoverished soils, the primary purpose of which will admittedly be a protective one while assisting in the restoration of the soil water supplies. But as the secondary objective, these forests will in time serve as the factory from which produce will be available to an increasing population returning to a formerly destroyed but now rejuvenated area.

These are neither visions nor dreams. But to understand the job and its possibilities, it will be at least necessary to allow those whose business in life it has been to study, consider, and interpret the factors concerned, to prescribe the possible practical remedial measures to be put into force and, in addition to the necessary funds, to ensure that a trained staff in the necessary numbers is forthcoming.

PRENATAL MORTALITY AND THE BIRTH-RATE

By Dr. A. S. PARKES, F.R.S.

National Institute for Medical Research, London

MAXIMUM reproductivity in a monogamous society requires that males and females of appropriate age shall be available in approximately equal numbers. A considerable excess of one sex or the other will decrease the reproduction-rate. In practice, there rarely seems to be an excess of males of this age; among European races a slight excess of females is usual. War, or other events involving a differential toll of men of reproductive age, naturally exaggerate the excess of females. In England and Wales before the War of 1914–18[1], there was an excess of some 649,000 or 8·7 per cent of females over males, at ages 20–45 years. For several years after 1918 the excess was more than a million, being about 1,050,000, or 13·4 per cent in 1925[2]. Ten years later, in 1935[3], the effects of the war were disappearing and the excess of females was down to 658,000, or 7·9 per cent, but it may well increase again considerably as a result of the present War. The surplus women, on statistical grounds alone, are evidently unable to get married in Great Britain, and the great majority of them, therefore, are sociologically sterilized. The number represents an appreciable percentage of the females of reproductive age, and this sociological sterility is a not inconsiderable factor in birth-rate problems. Groome[4] calculated that an increase in the net reproduction-rate of some 15 per cent would be expected to result from equalizing the numbers of males and females of reproductive age, even without any increase in the total population.

The only immediate solution of this problem of sociological sterility, whether due on a smaller scale to natural causes or on a larger scale to war, lies in a fundamental change in our social conventions. There are, however, other possibilities for a longer term policy. The excess of females is not found at all ages. In England and Wales, about 104 males are born to every 100 females. According to Russell[5] the mean ratio for 1838–1933 was 104·3, the range of yearly variation being about 103–106. The highest ratio was recorded in 1919, and this apparent effect of war conditions is confirmed by evidence from other countries and by the fact that during the present War the ratio has again risen to more than 106. The effect may well, as Martin[6] suggests, be due to lowering of the age of parents. The excess of males at birth is only temporary. Infant- and child-mortality fall differentially on the males, and the excess found at birth is abolished before or early in the reproductive period, and thereafter there is always an excess of females. The reduction in the infant and child mortality-rate has been associated with a raising of the age at which the excess of males disappears and a decrease in the excess of females in later age groups, but it is not certain that this factor will operate any further.

The purpose of this note is to lay emphasis on another aspect of the differential mortality problem, the prenatal wastage of lives, particularly of male lives. The amount of prenatal mortality from the time of conception to the time of birth is known to be considerable in many mammals, figures so high as 40 per cent or more having been determined. In man, the prenatal mortality cannot be estimated with any accuracy, but it is probably at least 20 per cent and may be much higher. Most of the information then available on this subject was summarized by me[7] some years ago.

This prenatal mortality in man will not depress the birth-rate to a corresponding extent, since it must often happen that, where fertility is good, the unsuccessful termination of one pregnancy allows of another one which would not otherwise have occurred. Nevertheless, it must exert a certain influence, and it is clear that a substantial decrease in prenatal mortality would lead to a rise in the birth-rate. More important, however, is the sex incidence of abortions, etc., which has been the subject of a number of researches. The earlier literature is summarized in the review referred to above. Almost all investigators agree that prenatal loss, like infant mortality but more so, falls differentially on the males. Auerbach[8], for example, found that there were 156 males per 100 females among more than 4,000 fœtuses aborted between the fourth and seventh months. The proportion of males was greater among the younger abortions. More recently, Russell[5] has given figures from American sources in which prenatal deaths under four months included 375 males per 100 females.

Two implications follow from observations such as these. First, it is quite clear that in man, as in some lower mammals, the proportion of males is much higher at conception than at birth. Anything approaching accuracy is impossible in the present state of our knowledge, but it is likely that in man there are at least 120 males to every 100 females at conception. This conclusion is curious in the light of the fact that X- and Y-spermatozoa are produced in equal numbers; but various explanations, which

are outside the scope of this article, can be offered. Secondly, it is evident that the amount of prenatal mortality must have considerable influence on the sex-ratio at birth. Many years ago, Tschuprow[9] concluded that the sex-ratio at birth was largely determined by the amount of prenatal mortality. This generalization requires various qualifications—allowance for the sex-ratio at conception, for example—but all subsequent work has tended to emphasize the influence on the sex-ratio at birth of the decrease in the proportion of males which takes place during the gestation period. For example, the greater number of males born to younger mothers is probably due to decreased prenatal mortality[10].

From the point of view of population problems, the important aspect, as Groome[4] pointed out, is that a substantial decrease in prenatal mortality would give an increase in the proportion of males born. If the sex-ratio at conception is 120, and 20 per cent of the fœtuses, having a sex-ratio of 200, die before term, then the ratio at birth will be a little more than 106. If the prenatal mortality were halved and retained the same sex incidence, the ratio at birth would be more than 113. Such an increase, coupled with the present reduction in infant mortality, would ensure an excess of males at reproductive ages and would do much to reduce or abolish the excess of females with no chance of marriage. This long-term effect would seem to be of real potential importance in counterbalancing the declining birth-rate, and an intensive programme of research on the causes and prevention of prenatal death offers one of the more promising medical contributions to the problem. Such a line of attack, unlike many projects designed to raise the birth-rate, could arouse opposition only from the sternest exponents of the principle of natural selection.

NEWS and VIEWS

Sir Napier Shaw, F.R.S.

On March 4 Sir Napier Shaw attains the age of ninety years. The present generation may be surprised to know that he had a distinguished career as a physicist before he took any part in meteorology. He was educated at King Edward's School, Birmingham, and at Emmanuel College, Cambridge, of which he was fellow during 1877–1906. He was University lecturer in experimental physics during 1887–99, and with Sir Richard Glazebrook was demonstrator in physics at the Cavendish Laboratory; their joint "Text-Book of Practical Physics" was a household word to students of physics of a generation ago. Sir Napier was elected to the Royal Society in 1891 and it was not until six years later that he was officially connected with meteorology, when he became a member of the Meteorological Council, a body responsible for the Meteorological Office. He became director of the Office in 1905. Then under his influence began a period of great advances in the science along many lines. He had the gift of stimulating the interest and enlisting the help not only of those working directly under him, but also of those outside his official orbit, and his ungrudging help is gratefully remembered by many.

Sir Napier retired from the Meteorological Office in 1920, but he did not retire from meteorology; in 1926 there appeared the first volume of his monumental "Manual of Meteorology", completed in 1931; a second edition of volume 2 appeared in 1936. A much enlarged and revised edition of his "Drama of the Weather" appeared so lately as 1939. These works show Sir Napier's energy at an age when many would have rested on their laurels. Honours have been showered on him by universities and societies both British and foreign. He was knighted in 1915. He was president of the International Meteorological Committee during 1907–23, of the Royal Meteorological Society during 1918–20, of Section A (Mathematical and Physical Sciences) of the British Association in 1908, and of Section L (Education) in 1919. In 1885 he married Sarah Harland, who ably helped him, whether when he was tutor of his College or later when he had to preside over meetings national and international; she died in 1923. Meteorologists and many others will join in all good wishes for Sir Napier's ninetieth birthday.

John Theophilus Desaguliers (1683–1744)

In the later years of Newton's life, there were few figures better known among the men of science in London than that of the short, thickset, near-sighted but broadminded and generous Frenchman, John Theophilus Desaguliers, who died on February 29 two hundred years ago in his lodgings near Covent Garden. Born at La Rochelle on March 12, 1683, he was brought to England by his father at the Revocation of the Edict of Nantes in 1685, and spent the remainder of his life here. At first his father was minister of the French chapel in Swallow Street, London, but also had a school at Islington. The son helped his father and then proceeded to Christ Church, Oxford, and after taking his degree qualified for the Church. In 1710 he was appointed successor to Keill as lecturer in natural philosophy at Hart Hall, and three years later removed to Westminster, living first in Channel Row and then over the Bedford Coffee House, lecturing with great success year after year to "persons of all ranks and professions and even the ladies". He gained a reputation, too, by his translation of s'Gravesande's "Elements of Natural Philosophy". For many years he was demonstrator to the Royal Society and it was to him that the first actual Copley Medal was given, although both he and Stephen Gray had previously received monetary awards under the Copley bequest. As a clergyman he held various livings, one of these being that of Whitchurch, Middlesex, of the church of which Handel was organist. In his works he gives full particulars of the many experiments he made and also much information about the principal mechanical constructions of his time. His death took place when he was nearly sixty-one, and he was buried in the Savoy. One of his sons, Thomas Desaguliers (died 1788), for many years superintended Woolwich Arsenal, and was the first scientific investigator into gunnery in the British Army.

Pascal's Arithmometer

At a well-attended meeting of the Newcomen Society held in the rooms of the Royal Society on February 16, Mr. R. Nilsson gave a paper entitled "The Pascal Arithmometer and Other Means to Solve Mathematical Problems". The audience included many distinguished foreigners. Premising that accuracy in calculation is one of the most important elements in scientific progress, Mr. Nilsson said that by a calculating machine is understood a great number of working parts conjoined in action by various mechanisms to obtain arithmetical or algebraic results. Describing in detail, with the use of slides, the arithmometer invented by Blaise Pascal (1623–62) when a youth of nineteen, the author said that Pascal's basic invention was the 'ten-carry-over' which is seen in the counters, meters, cash registers, etc., which are part and parcel of our daily life. Two years were occupied in making the first machine, and more than fifty models were constructed before the machine was in working order. Pascal showed it in 1647 to Descartes and in 1649 to Chancellor Séguier, who helped him to obtain a patent. Mr. Nilsson mentioned the machines which succeeded Pascal's; Sir Samuel Morland's (1666), that of Leibniz (1672), and those of Grillet, Poleni and Charles Xavier Thomas, of Colmar, Alsace, who began the manufacture of calculating machines. In the ante-room was a representative exhibition of machines and documents. In proposing a vote of thanks to the Royal Society for its hospitality, the chairman, Eng. Captain E. C. Smith, said that there could be no more suitable place for the gathering. Pascal was associated with some of the French men of science whose meetings led to the founding of the French Academy of Sciences, and his death coincided with the grant of the Act of Incorporation to the Royal Society.

Ankara University: Opening of Faculty of Science

A new Faculty of Science in the University of Ankara was opened on November 8, 1943, in the presence of President Inönü. The President, accompanied by the Prime Minister, Sükrü Saracoglu, was welcomed at the inauguration ceremony by the chairman of the National Assembly, B. B. Abdülhalik Renda. All the members of the Cabinet were present; Mr. R. F. Lucas, of the British Council, was also invited to attend the ceremony. The Minister of Education, Hasan Ali Yücel, in his opening address, referred to Turkish progress during the twenty years since the establishment of the Republic. The consequent changes in the national outlook have developed a need for scientific and technical training which is now enhanced by the mechanization of armed forces in a world at war. Hitherto Turkish educational institutions have lacked equipment for practical training; but Turkey has now an established policy of education based on positive knowledge to reinforce the earlier practice of theoretical training only. The nation needs mechanical engineers, mining and civil engineers, and the great problem of Turkey to-day is to find the means for training students in large enough numbers to satisfy the national requirements without reducing the educational standard. The Government is keenly aware of these needs and has sanctioned the establishment of this faculty as a step to meet them. The assembly was later addressed by the Rector of the Faculty, by a student, and by Prof. Kerim Erin, of the Faculty of Science, University of Istanbul.

The new Faculty is temporarily installed in the Gazi Teachers' Training Institute. The Dean of the Faculty, Bay Hayri Dener, is also professor of physics, and a member of the Board of Education. The chair of chemistry and the presidency of the new Chemistry Institute of the Faculty is held by Dr. Avni Refik Bekman. The Ministry of Education has invited the British Council to nominate British candidates for a professorship in each of the existing Departments of Chemistry, Physics and Mathematics. The establishment of this Faculty thus implements the approval of the Bill recently presented by the Turkish Cabinet to the Chamber of Deputies.

Science in China

A pamphlet entitled "The Place of Science in China" by Yap Pow-Meng, honorary secretary of the National Science Society of China, British Branch, published by the China Campaign Committee, 34 Victoria Street, London, S.W.1 (*6d.*), attributes the failure of the scientific method to establish itself in the intellectual tradition of China mainly to social and economic reasons. From the first, the makers of the revolution of 1911 seized upon science as a means of achieving their ideal of a progressive, industrialized China, and the pamphlet gives a brief account of the organization of education in science, of scientific research institutions, including the Academia Sinica, which is essentially an organization providing facilities for scientific research, the National Academy of Peiping, the Science Society of China, the National Science Society of China, the Fan Memorial Institute of Biology, the Henry Lester Institute for Medical Research, and private technical research institutions, of which the most important is the Hangwai Institute of Industrial Chemistry.

The majority of the research institutions of China were founded in the coastal areas and have now been moved to the west and south-west. Apart from those of the Radium Institute of the Peiping Academy and the Metals Research Institute and Science School of the National Tsing-hua University, Chinese researches in physics and chemistry have not so far been impressive, and in China as elsewhere experimental psychology has not made a complete break from the old philosophical psychology. The pamphlet also includes some account of the organization of science in China's war effort under the National Economic Council, the Ministry of Economic Affairs, the National Resources Commission, the Ministry of Agriculture and Forestry, the National Geological Survey and the National Health Administration, as well of the attempts being made to overcome educational difficulties due to the War.

Isinglass as a Substitute for Human Blood Plasma

Many substances have been tried as substitutes for human blood plasma. Recently (Nature, **153**, 145; 1944) reference was made to the use of 'despeciated bovine serum'. A recent note (*Edin. Med. J.*, **50**, 758; 1943) describes the use of isinglass, which is available in sufficient quantities and can be cheaply prepared, as a substitute for human blood plasma. Its injection causes no antigenic response. Prof. N. B. Taylor and Miss M. S. Moorhouse (*Canad. Med. Assoc. J.*, **49**, 251; 1943) transfused 25 dogs from which 47–71 per cent of the blood had been bled, with 4 or 6 per cent solutions of isinglass, and most of the dogs made a complete and uneventful recovery. Repeated injections over a period of weeks caused

no changes in the viscera, and isinglass does not interfere with the normal regeneration of the blood plasma. H. E. Pugsley and R. F. Farquharson (*Canad. Med. Assoc. J.*, 49, 262; 1943) gave the isinglass solution 58 times to 51 human patients to test it for pyrogenic and other toxic effects. A slight rise of temperature occurred on eight occasions, but no other unfavourable signs were noted in the other cases. When the isinglass was given to patients suffering from acute hæmorrhage, extensive burns, compound fractures and severe circulatory failure, the results were all good, and there were no toxic effects. The amount given varied from 200 c.c. to an infant to 8,800 c.c., given over a period of three days, to an adult.

Oil from the Sunflower Plants

There are probably few countries of the temperate regions which have a superabundance of fats and oils. War-time conditions, moreover, always accentuate any deficiency, and turn attention upon the possibilities of home production. A recent paper by E. F. Hurt (*J. Roy. Hort. Soc.*, 68, Part 11; Nov. 1943) gives the results of experience with the sunflower crop. Oil from the seeds of this crop is useful for edible and culinary purposes, for making margarine, as food for cattle and poultry, for canning fish and making fine soap. Its gastronomic value is equal to the finest olive oil. The crop is widely tolerant of soil types, but removes large quantities of soil nutrients, most of which are retained in the stalk, and can be returned to the ground after harvest. Sowing the seed at an even depth of 1½–2 in. appears to be important, and 7½ lb. of seed is needed to sow an acre by drill. Sunflower is a good cleaning crop, and appears to be but little affected by disease, though it is susceptible to wireworm attack and the depredations of birds at harvest time. Three semi-dwarf varieties—'Mars', 'Pole Star' and 'Southern Cross'—are suggested for Great Britain, and as the supply of fats and oils may be one of the most acute of post-war agricultural problems, the crop appears worthy of more extended trial.

Thermoplastic Electric Cables

A PAPER on thermoplastic cables, read by Dr. H. Barron, J. N. Dean and T. R. Scott on February 10 before the Institution of Electrical Engineers, reviews the circumstances which have led to a considerable increase in the use of thermoplastic cables within the last few months. It is pointed out that the relative importance of such cables cannot yet be evaluated on a peace-time basis, for the economic level cannot be established and also synthetic rubber is now making its appearance. In order to establish a basis for evaluation, it is desirable to have a thorough understanding of the general characteristics of thermoplastic cables; this is attempted in the paper with particular reference to polyvinyl chloride cables. Indications are given of the polymer situation, the definition of a thermoplastic material and the resulting implications. The building-up and testing of polyvinyl compounds is discussed, and the manufacture, characteristics and uses of cables derived therefrom are considered in detail. A brief survey of other thermoplastics is followed by a comparison of polyvinyl chloride with rubber.

It is concluded that suitably selected thermoplastic compounds can produce satisfactory wires and cables the characteristics of which are such that the corresponding rubber cables can be replaced by these thermoplastic cables. Oxidation need no longer be considered as the predominant factor in determining life; there are still restricting factors which prevent thermoplastic cables from being worked at temperatures appreciably in excess of those suitable for rubber cables; but these factors are of a different nature and may be countered by development and design along lines which would be impracticable for rubber. The cable engineer has acquired a range of alternate materials which, while they present problems of their own, promise interesting solutions for some existing problems. A period of rapid development of wires and cables of compound characteristics must inevitably ensue so soon as free choice, on an economic basis, of such materials is practicable.

Industrial Fire Risks

IN a paper read in London on December 9 before the Institution of Electrical Engineers, Messrs. W. Fordham Cooper and F. H. Mann describe first the classification of buildings and structural materials in relation to fire resistance, and then deal with the hazard from various industrial materials and processes and the special precautions which should be adopted in providing and operating electrical installations in view of these risks. Flame-proof and intrinsically safe constructions are briefly described. The second part of the paper illustrates the application of the matter discussed in the first part; but, as it is impossible to deal with every risk, attention has been particularly paid to the heavy chemical (gas, coke and by-product) and textile industries by way of examples, although some other matters, notably switch and transformer oil-fire risks, are also mentioned.

Tuberculosis in Paraguay

IN a recent article (*Bol. Of. San. Panamer.*, 22, 318; 1943), Drs. A. R. Ginés, A. Alvarez and M. Mercado state that in June 1941 the control of tuberculosis in Asunción was started under the direction of Dr. Angel R. Ginés, and 40,000 persons were examined in the course of a year. In November 1941, the Ministry of Health amended a decree of 1938 making compulsory the X-ray examination of all public officers, public and private employees, teachers, students, labourers, etc. The examination consisted of a tuberculin test, pulmonary röntgenograms or sometimes merely fluoroscopy and a rapid examination of the skin and mucous membranes. The Tuberculosis Dispensary at Asunción, which was founded in 1922, during the first ten years of its existence could treat only general advanced tuberculosis owing to the lack of modern means of diagnosis; but in 1932 a chair of tuberculosis was created and the campaign against tuberculosis now includes a röntgenological and tuberculin survey and a morbidity and mortality survey in the urban areas of the Republic, diagnosis of the disease by modern methods, effective isolation or quarantine of contagious cases, creation of schools for the tuberculous or pre-tuberculous, vaccination of the newborn with B.C.G., economic and social improvements, creation of an Institute of Social Security, intensive educational propaganda, and eradication of tuberculous animals. The tuberculosis death-rate is calculated to be 199·9 per 100,000, and its relation to general mortality is 15·50 per cent. Tuberculosis with other diseases of the lungs caused a third of the deaths in 1941. Relation to the standard of living is supported by the following death-rates:

merchants 3 per cent, intellectuals 6 per cent, seamstresses, domestic helpers and other employees 10–11 per cent, farmers 22 per cent and labourers 29 per cent. The highest death-rates were noted in the 1–5 year old group and in the 20–40 group.

Immunizations in Large Cities of the United States

In a recent paper (*Public Health Rep.*, 58, 1121; 1943), Selwyn D. Collins, head statistician, and Clara Councill, assistant statistician of the United States Public Health Service, record their study of immunization against diphtheria, smallpox, scarlet fever and typhoid fever based on a canvas of 213,931 households in 23 cities of 100,000 or more inhabitants. Their conclusions are as follows. Immunizations against scarlet fever and typhoid fever are negligible compared with those against diphtheria and smallpox. In the pre-school age immunizations against diphtheria are more frequent than vaccinations against small-pox, but after five years the reverse is true. There was considerable geographical variation in the extent of immunization against the diseases. In the north, for example, the percentages of native, foreign and coloured children of specific ages immunized against diphtheria are approximately the same, while in the south a higher percentage of the native whites is immunized than of the foreign whites or coloured.

Cattle Fodder from Wood

According to an annotation entitled "Fir to Fodder" in the January issue of the *Anglo-Swedish Review*, the Swedish forests provide a practically inexhaustible store of timber which can be converted into fodder for horses and cattle. It can be made from the wood of the fir tree, but pine can also be used. The raw wood has no food value for man, even if ground to a fine flour, as there are no enzymes or micro-organisms in the human digestive tract to dissolve the wood and its cellulose. Cattle and horses, however, can absorb it almost entirely because their digestive organs contain bacteria which can break down the pure cellulose into products which can be absorbed into the blood. To make the fodder cellulose more nutritive and palatable to animals, molasses and sometimes phosphates or salts are added at the pulp mill. Alcohol is also obtained during the process of making fodder pulp.

Research in Human Nutrition

The Medical Research Council has established a Unit for Research in Human Nutrition as part of its staff organization, and Dr. B. S. Platt has been appointed its director. Temporary accommodation has been provided at the National Hospital for Nervous Diseases, Queen Square, London. Some part of the investigations undertaken by the Unit will be directed towards nutrition problems in the tropics. Among other things, Dr. Platt will continue the work, for which he joined the Council's staff in 1938, of co-ordinating a programme of nutritional investigations in the Colonies by arrangement between the Colonial Office and the Council.

Properties and Uses of Diamonds

A research department has been established by the Diamond Trading Company, Ltd., the London office of which is at 32–34 Holborn Viaduct, London, E.C., under the management of Mr. Paul Grodzinski, assisted by a staff of five. The Department is engaged in investigations into the properties of diamonds, their preparation for use and, in particular, their application in industry. An extensive library, built up over a long period of years by Mr. Grodzinski, forms part of the Department, and its information service is available free of charge.

The Night Sky in March

Full moon occurs on March 10d. 00h. 28m. U.T., and new moon on March 24d. 11h. 36m. The following conjunctions with the moon take place: March 2d. 08h., Mars 6° N.; March 2d. 13h., Saturn 3° N.; March 7d. 11h., Jupiter 0·1° S.; March 22d. 16h., Venus 2° N.; March 29d. 23h., Saturn 2° N.; March 30d. 18h., Mars 5° N. The following occultations of stars brighter than magnitude 6 take place: March 3d. 19h. 59·4m., ν Gemi. (*D*); March 28d. 20h. 31·1m., 63 Tauri (*D*); March 31d. 19h. 23·5m., ζ Gemi (*D*). The times refer to Greenwich and *D* refers to disappearance. Mercury rises at 6h. 44m. and 6h. 05m. at the beginning and end of the month, but is too close to the sun for good observation. The planet is in superior conjunction on March 17. Venus, a morning star, rises at 5h. 34m. and 5h. 14m. at the beginning and end of the month, and can be seen only with difficulty. Mars sets at 2h. 54m. and 2h. at the beginning and end of the month and can be seen in the early part of the night. On March 7d. 15h. there is a conjunction between Mars and Saturn, Mars being 3·4° N. Jupiter is visible throughout the night, setting at 6h. 15m. and 4h. 13m. at the beginning and end of the month. Saturn is visible in the early part of the night, setting at 2h. 40m. and 0h. 49m. at the beginning and end of the month. Spring equinox begins on March 20d. 18h.

Announcements

Dr. Harry R. Ricardo, the well-known consulting engineer and authority on the internal combustion engine, has been elected president of the Institution of Mechanical Engineers for the year 1944–45.

J. P. Rutland (*New Phyt.*, 40, 210; 1941) has published a supplement to the Merton Catalogue of Chromosomes of British Plants. The new list contains about a hundred new chromosome numbers discovered by the author and other workers, and is a valuable contribution to the analysis of the British flora.

The following appointments have recently been made in the Colonial Service: H. Doggett to be agricultural officer, Tanganyika; A. J. Browning to be assistant conservator of forests, Sierra Leone; S. L. Finding to be assistant conservator of forests, British Honduras; H. Tordoff to be assistant conservator of forests, Trinidad; A. W. Vaughan to be veterinary officer, Jamaica; Dr. E. F. Thompson to be fishery officer, Jamaica; D. W. Duthie (chemist, British Guiana) to be soil chemist, East African Agricultural Research Bureau, Tanganyika; A. F. A. Lamb (assistant conservator of forests, Nigeria) to be senior assistant conservator of forests, British Honduras.

Erratum. In the paragraph entitled "Road Research" in Nature of February 12, p. 193, the names of Major H. E. Aldington (chairman) and Mr. W. Savage were inadvertently omitted from the list of members of the committee.

Nature of Peptones

IN a letter published in NATURE[1], a method was described by us whereby the ratio

$$\frac{\text{N-total cleavable}}{\text{N-split hydrolytically}}$$

may be easily computed, and hence the extent of cleavage which has been performed by one or several proteinases acting on a given protein or peptone determined. Since then, still more proteins and peptones have been investigated and it seems desirable to give a brief account of the results achieved. It should be emphasized beforehand, however, that the proteins investigated by us generally showed the same behaviour as regards their cleavability by the proteinases employed irrespective of their physical-chemical properties, chemical composition and source of occurrence, as indicated in Table 1 below.

(1) The ratio $\frac{\text{N-total cleavable}}{\text{N-split hydrolytically}}$ as obtained by exhaustive cleavage with pepsin-hydrochloric acid was in all cases equivalent to a Z value of 4 with the sole exception of casein (Table 1).

TABLE 1.

Substrate	Cleaved exhaustively by	N-total cleavable / N-split hydrolytically
Ovalbumin-pepsin peptone	Pepsin-hydrochloric acid	4·02
,, ,, ,,	Pancreatic proteinase	4·02
Pancreatin proteinase peptone from ovalbumin (cleaved exhaustively)	—	3·96
Fibrin pepsin peptone	Pepsin-hydrochloric acid	4·10
Casein pepsin peptone	,, ,, ,,	4·82
,, ,, ,,	Pancreatic proteinase	3·93
Pancreatic proteinase-peptone from casein	Pancreatic proteinase	3·82

(2) All peptones obtained from proteins by incomplete splitting with pepsin-hydrochloric acid (thus leaving a substantial margin for further action by additional enzyme) are split by the succeeding action of purified pancreatic proteinase (tested as to its freedom from protaminase and polypeptidases) to the above ratio of 4 (Table 1).

(3) Exhaustive cleavage by pepsin-hydrochloric acid followed by exhaustive cleavage by pancreatic proteinase reduced the above ratio in all cases to a value of 3 (Table 2).

TABLE 2.

Substrate	Cleaved exhaustively by	N-total cleavable / N-split hydrolytically
Ovalbumin pepsin peptone	Pepsin-hydrochloric acid followed by exhaustive cleavage with pancreatic proteinase	3·18
Casein pepsin peptone	,, ,, ,,	3·10
Fibrin pepsin peptone	,, ,, ,,	3·09

(4) Proteins split by the action of pancreatic proteinase alone were found to give the same nitrogen ratio as obtained by the action of pepsin-hydrochloric acid, namely, 4 (Table 1).

These results are summarized in the accompanying tables.

The peptones prepared from proteins by cleavage with pepsin-hydrochloric acid as shown in Table 1 were not subjected to exhaustive splitting during the process of preparation, since this would involve the addition of substantial amounts of enzyme carrier protein which might cause aberrations from the real N-values, etc., of the substrates investigated. The further degree of cleavage which might be performed by this enzyme or any other proteinase employed in succession had always been observed in enzyme tests and added to the N-value corresponding to the free (NH_2 + NH)-groups found in the peptone (see ref. 1).

A detailed report will be given elsewhere.

Growth Stimulation of *L. casei* E. by Pyrimidines

PURINE and pyrimidine derivatives have been shown to be growth stimulators for a number of organisms; uracil has been shown necessary for *L. arabinosus* and *Leuconostic mesenteroides*[1], and the anaerobic growth of *Staph. aureus*[2], thymine for *S. Lactis*[1], adenine for *L. arab.*, *L. pentosus*[1], and adenine and guanine for *L. plantarum*[3]. Adenine, guanine, uracil and xanthine have been included in media for the growth of *L. casei*[4,5], and Feeney and Strong[6] have shown adenine and guanine to be stimulatory for *L. casei* E. under certain conditions.

During work on the purification of unknown factors present in liver and required for the growth of *L. casei* E., it was found that the active material displayed properties which suggested the presence of purine or pyrimidine derivatives, and accordingly a number of synthetic compounds were tested for growth-promoting activity. Of those tried only one was found to give any response, namely, orotic acid (uracil 4-carboxylic acid).

A casein hydrolysate basal medium was used, the same as that described by Chattaway, Happold and Sandford[7] with the inclusion of riboflavin (40 μgm./l.) and biotin (5 μgm./l.) and without the addition of a liver eluate. The inoculation was a loopful of a faintly opalescent suspension of bacterial cells in sterile water, and growth was estimated by titration of the lactic acid produced after 72 hr. incubation at 37° C., using brom-thymol blue as indicator. Titrations from 0·5–2 c.c. N/10 lactic acid have been repeatedly obtained with the derivative mentioned in a minimum concentration of 0·01 μgm./ml. medium, with no growth in control flasks. The response has varied from time to time and on a few occasions there has been no response, and this is ascribed to variations in the casein hydrolysate used, since the concentration of unknown factors in the hydrolysate may vary. Substances which have been found not to

stimulate acid production either alone or in combination and in concentrations ranging from 20 to 0·01 μgm./ml. are adenine, guanine, uracil, thymine, 4-methyl-5-ethoxymethyl uracil, 4-methyl-4:5-dihydro-uracil, 2-methyl-4-amino-5-aminomethyl pyrimidine, 4-methyl-5-amino-uracil and 4-methyl-uracil.

I should like to thank Prof. A. R. Todd and Dr. F. Bergel, of Roche Products Ltd., for supplies of materials, and Dr. F. C. Happold for helpful advice.

Importance of Pyrimidine Derivatives in the Growth of Group C (Lancefield) Streptococci upon a Simplified Medium

RICHARDSON[1] showed that uracil (2.6 dihydroxy pyrimidine) is necessary for the anaerobic growth of *Staphylococcus aureus*, and more recently Snell and Mitchell[2] have reported that purine and pyrimidine derivatives stimulate the growth of certain lactic acid bacteria. Möller[3] had previously claimed that adenine and guanine increase the growth of *Lactobacillus plantanum*. Pappenheimer and Hottle[4] showed that uracil is not necessary for the growth of a strain of hæmolytic streptococcus Group *A*. The latter authors reported, however, that purine derivatives are necessary for this organism unless the carbon dioxide tension in the atmosphere above the culture is high. At a partial pressure of 40 mm. mercury of this gas, rapid and optimal growth occurs without the addition of purines to the medium.

It was found here that a strain of Group *C* (Lancefield) type 7 (Griffiths) hæmolytic streptococcus (called *C*7) gave only slight and variable growth upon a casein hydrolysate medium unless this was supplemented by uracil. The casein hydrolysate basal medium was similar to that designed by Bernheimer, Gillman, Hottle and Pappenheimer[5], except that biotin, which is not necessary for the growth of *C*7 upon the casein medium, was omitted. Bicarbonate, and, of course, uracil were also not added. The growth-factors present were thiamine, nicotinic acid, pyridoxin, calcium pantothenate, riboflavine, adenine and glutamine. It is probable that not all these factors were necessary for the growth of the organism, but they were included in the medium for completeness. The glucose concentration was 0·25 per cent.

Two inocula were used: the first (I) was three drops of faintly opalescent suspension of bacterial cells in isotonic saline per 10 ml. of medium. The cells were from a 6–7 hour broth culture of *C*7 and were twice washed with saline. The second inoculum (II) was three drops of a 1/100 dilution of (I) per 10 ml. of medium.

Table 1 shows the mass of growth, as milligrams of bacterial N per 50 ml. of culture, after twenty-four hours incubation at 37° C. in the medium supplemented by uracil or orotic acid (uracil-4-carboxylic acid).

TABLE 1. INFLUENCE OF ADDING VARIOUS AMOUNTS OF URACIL AND OROTIC ACID TO THE BASAL MEDIUM, UPON THE GROWTH OF STREPTOCOCCUS *C*7.

Mgm. of uracil or orotic acid added per 10 ml. of medium	Growth in mgm. bact. N per 50 ml. of medium					
	Inoculum I			Inoculum II		
	Uracil		Orotic acid	Uracil		Orotic acid
	Exp. *a*	Exp. *b*	Exp. *a*	Exp *a*	Exp. *b*	Exp. *a*
0	5·9	2·3	6·6	3·8	0·7	3·9
0·005	—	3·4	6·1	5·2	0·7	3·5
0·02	9·2	6·0	7·4	8·1	3·5	7·5
0·10	12·5	—	11 5	—	—	10·8
0·20	10·0	8·6	10·2	10·0	10 0	11·2

The amount of growth which occurred in the media containing only small amounts of the pyrimidine derivatives was variable but did not increase during a further twelve days incubation. The addition to the medium of 10–20 μgm./ml. of uracil or orotic acid, however, resulted in growth as good as that in peptone broth cultures.

Increased carbon dioxide tension up to 50 mm. mercury had no influence on the mass of growth that occurred in any of the media. Complete removal of carbon dioxide from the atmosphere above the culture inhibited the growth of inoculum II but not I, even in the presence of 20 μgm./ml. of uracil.

Four out of five of the strains of Group *C* streptococci of various types which were tested also needed uracil or orotic acid for optimal growth. The two pyrimidine derivatives were equally effective in increasing both the rate and mass of growth of these organisms. Table 2 summarizes these results and includes *C*7 for comparison.

TABLE 2. INFLUENCE OF URACIL AND OROTIC ACID (EACH AT A CONCENTRATION OF 0·10 MGM. PER 10 ML. OF MEDIUM) UPON THE RATE AND MASS OF GROWTH OF GROUP C STREPTOCOCCI. THE INOCULUM USED WAS OF STRENGTH II ABOVE.

Strain	Basal medium		Basal medium + uracil		Basal medium + orotic acid	
	M	*T*	*M*	*T*	*M*	*T*
Mare (2)	++	4 days	++++	40 hr.	++++	40 hr.
Mare (3)	+	5 ,,	++++	20 ,,	++++	20 ,,

Sodium Sulphate as an Agent Causing the Development of the 'Chloride-secreting Cells' in Macropodus

IN an earlier paper[1], I have reported the enormous development of the 'chloride-secreting cells' in the branchial lamellæ of the paradise fish acclimatized in a table-salt solution of salinity 27·3 per cent. As these cells are very scanty and rudimentary in the control specimens, the conclusion was drawn, in harmony with the suggestion of Keys and Willmer[2], that they are intimately concerned in the undertaking of osmotic regulation against a hypertonic external medium. The question now arises as to whether the secretory activity of these cells is restricted to chloride alone, as their name implies, or is of a more general nature, capable of turning out salts other than chloride.

To shed light on this problem, I have conducted an acclimatization experiment on *Macropodus opercularis* similar to that described in the earlier paper (*vide supra*), except that Merck's extra pure crystals of Glauber's salt ($Na_2SO_4.10H_2O$) was employed in substitution for the table-salt. Commencing on March 12, 1942, 0·5 gm. of that salt was introduced daily into the 3,000 c.c. jar, which housed four individuals, until May 10 inclusive. Then the daily dose was increased to 1 gm. from May 11 to May 20 inclusive, to 2 gm. from May 21 to June 9 inclusive, to 3 gm. from June 10 to June 19 inclusive, and up to 4 gm. from June 20 to June 24 inclusive. At the close of the course of acclimatization, the *milieu extérieur* was composed of a Glauber's salt solution of 3·83 per cent strength (since a total of 115 gm. had been dissolved in 3,000 c.c. of water), and in this the fish lived, apparently with depressed appetite, for four days before they were killed and their gills fixed (on June 29). Microscopic examination revealed quite a number of the 'chloride-secreting cells' at the base of the branchial lamellæ, the larger ones of which sometimes measured $12\mu \times 9\mu$ in size. Although not so prominent as those acclimatized in the table-salt solution, these cells are clearly evident and much more well-developed in comparison with the control specimen, so it is scarcely possible for them to be wrongly identified.

The result thus obtained points to a non-specificity of the secretory activity of these cells. As the external medium is practically chloride-free and owes its osmotic gradient exclusively to the sulphate, there is no reason to think that these cells should secrete chloride instead of sulphate under such a condition. The development of such cells in a hypertonic sulphate solution can most easily be interpreted on the assumption that these cells are secreting the sulphate, for in this way water could be freed and osmo-regulation effected. Accordingly, I suggest that the substance destined to be secreted would not necessarily be chloride in all instances, but would vary according to the chemical nature of the environment, and would probably correspond to the osmotically active substance in the external medium. In the case of a marine environment, the osmotically active substance is naturally the chloride, hence chloride is secreted by these cells[3]. In the present experiment, however, sulphate should be expected, inasmuch as it is the only osmotically active substance present.

That the 'chloride-secreting cells' develop in response to a sulphate medium tends to weaken the conclusion reached by Smith[4] that "SO_4, like Ca, Mg and PO_4, is excreted exclusively by the kidneys". According to his opinion, sulphate should combine with sodium, to be excreted afterwards by the kidney, as he puts it : "In the absence of other salts, SO_4 takes Na into the urine with it, . . ." If so, then the burden of osmotic regulation in a hypertonic sulphate solution would appear to have been borne by the renal organs rather than the gills. But this is wellnigh impossible in view of the osmotic limitation of the fish kidney. Based on the result of the present experiment, considering the 'chloride-secreting cells' as the anatomical basis for hypertonic excretion, I suggest that divalent ions, at least the sulphate, might also be secreted extra-renally by these cells. Determination of the secretion of these cells by direct chemical methods is much required to settle this question.

I wish to express my gratitude to Dr. H. W. Wu, at whose suggestion the present work was carried out.

Congenital Porphyria in Pigs

CONGENITAL porphyria in animals was first described by Fourie and Rimington[1], who found the condition in cattle in South Africa. The most striking features of the disease are the colour of the bones due to the deposition of uroporphyrin and other pigments, and the excretion of considerable amounts of porphyrin in urine and faeces. The finding of such pigmented bones in cattle and swine in slaughterhouses has been reported from time to time (for review see ref. 2), but so far as we are aware no living domestic animals other than South African cattle have been available for study.

Recently, some pig bones showing a reddish-brown discoloration were sent to the Animal Research Station, Wallaceville, by Mr. J. A. Chenery, supervising meat inspector at Waitara. The bones gave a brilliant red fluorescence in ultra-violet light and were found to contain uroporphyrin I. Congenital porphyria was therefore suspected. When a second pig from the same farm was found to show similar symptoms, it was possible to trace the sow which was producing offspring with pigmented bones. A urine sample from this sow was dark red, with absorption bands, after acidification, at 555 and 600 mμ, and on extraction yielded uroporphyrin I and coproporphyrin I, together with small amounts of the series III isomers. The fæces contained coproporphyrin I and traces of coproporphyrin III.

Full details of the chemical examination of material from this sow and affected progeny will be given elsewhere ; here it is sufficient to state that the nature and type of the porphyrins obtained resemble those found in human and bovine congenital porphyria. The sow appears to be the first living case of congenital porphyria in pigs which has been examined.

Fourie[3] has shown that in South African cattle the disease is inherited as a recessive character. Information so far available on the breeding of the pigs is incomplete, and no conclusions as to the mode of inheritance can be drawn. The affected sow is of mixed breeding, out of a Tamworth-Berkshire-

Large Black dam by a pedigree Tamworth sire. When first examined she had produced two litters by a Tamworth boar (Boar *A*), and has since given birth to a third litter by another Tamworth (Boar *B*) which is a half-brother, on the sire's side, to Boar *A*. Such details as can be obtained on the occurrence of offspring with pigmented bones in these three litters are given in the following table:

Litter	No. in litter	Pigmented	Normal	No information	Sire
1	10	1	–	9	Boar *A*
2	10	2	3	5	Boar *A*
3	7	2	5	0	Boar *B*

A full sister to the affected sow, mated to Boar *B*, produced 14 pigs none of which had coloured bones. Both boars appear to be clinically normal.

The porphyria sow shows no symptoms of the photosensitivity which often accompanies congenital porphyria; but as she is black all over, this is not unexpected.

The sow and Boar *A* have both been purchased by this Research Station for breeding experiments and chemical studies.

Treatment of a Virus Disease of Chickens with Sulphonamides

BLAKEMORE has published[1] an account of a disease produced in young chicks by the inoculation of suspensions of tissues from typical cases of fowl paralysis (neurolymphomatosis). While the lesions were superficially unlike those of typical fowl paralysis, the course and pathology suggested that the experimentally produced disease was an acute form of fowl paralysis. Glover[2] produced a similar disease in chickens by the inoculation of tissue suspensions from a turkey affected with neurolymphomatosis. It was shown that the infective agent was filterable[3]. During the course of experiments which have been carried out in this Laboratory, a number of strains of virus which originated from paralysed fowls have been studied. Intraperitoneal inoculation of young chicks with virus results in the production of lesions which are primarily necrotic and are most conspicuous in the liver and heart. Visceral lesions become visible to the naked eye 48–72 hours after inoculation. They increase in extent and frequently reach maximum severity 6–8 days after infection. In the experiments recorded here, all chicks were killed 5–10 days after infection. Diagnosis was based upon the presence or absence of macroscopic lesions.

The influence of sulphonamides in the treatment of this disease has been striking. For ease of administration the sulphonamides have been mixed into the food or dissolved in the drinking water. Chickens treated continuously from the time of inoculation until the time of killing failed to develop lesions and their tissues proved to be non-infective. Treatment commenced at the time gross lesions were established resulted in the arrest and resolution of the disease process. A total of 138 chicks inoculated with eighteen strains of virus have been treated with sulphadiazine mixed in the food at a level of $\frac{1}{24}$–$\frac{1}{8}$ gm. per oz. None has developed macroscopic lesions. Of 117 control infected untreated chicks, 101 showed gross lesions on post-mortem examination.

The disease is sensitive to treatment with most of the sulphonamides in common use. As judged by the smallest dose necessary to prevent the development of gross lesions, the value in descending order is sulphadiazine, sulphamezathine, sulphathiazole, sulphapyridine, sulphaguanidine. The toxicity of sulphanilamide to chicks is such that it proved valueless.

The action of sulphonamides in this condition appears to be similar to that in bacterial infections. It is neutralized by *p*-aminobenzoic acid. A virus-containing suspension remained infective for more than twenty-four hours when prepared in a saturated aqueous solution of sulphathiazole and kept at room temperature.

The observation that this virus disease responds to sulphonamide treatment is of special interest, since apart from lymphogranuloma inguinale and possibly trachoma, virus diseases have proved refractory to chemotherapy.

The effect of sulphonamide treatment on the clinical condition and infectivity of fowls affected with typical fowl paralysis is being studied. It is clear that much careful work will be required in order to determine if means exist whereby sulphonamides might be employed in an attempt to control fowl paralysis. The low economic value of the individual fowl imposes obvious limitations upon the medical treatment of the diseases of poultry.

Urease Activity and Ascorbic Acid

IN a recent note, Elson[1] has shown that ascorbic acid at low concentrations inhibits urease activity, and that this inhibition is prevented by addition of cysteine. Quastel[2] suggests that the inhibition of the activity by ascorbic acid is due to the oxidized form of ascorbic acid, namely, the diketone (dehydroascorbic acid) and not to the ascorbic acid itself. The disappearance of the inhibition on the addition of cysteine has been attributed to the reduction of the dehydroascorbic acid to the inert ascorbic acid. It seemed to us more probable that the action of ascorbic acid is not connected with either ascorbic acid or dehydroascorbic acid, but with the oxidation of the vitamin by traces of heavy metals like copper present in the reaction mixture. For several years we have been investigating the influence of ascorbic acid on enzymes, and we have obtained results showing that the vitamin as such or the dehydroascorbic acid has very little influence on the enzymes (phosphatases and amylase); but when the vitamin is oxidized by traces of copper present in the reaction mixture the enzyme is inhibited to a considerable extent. It was also found that substances which inhibit the oxidation of ascorbic acid annul the inhibition by the vitamin. In the light of these results we have now investigated the influence of ascorbic acid,

dehydroascorbic acid and substances which inhibit the oxidation of the vitamin, on urease. The experimental method adopted was as follows.

Briefly, it consists in incubating a mixture of solution containing 0·5 c.c. of urease (prepared by extraction of jack bean powder with water), 3 c.c. acetate buffer $M/5$, pH 6·0 and the substance under investigation in a total volume of 8·0 c.c. for 30 min. at 30° C. At the end of this period, urea (2 c.c. of 3 per cent) was added to the mixture, and the ammonia formed at the termination of a subsequent 30 min. incubation at 30° C. was estimated by the usual aeration method. Representative results showing the effect of ascorbic acid, dehydroascorbic acid and substances which inhibit the oxidation of the vitamin on the activity of the enzyme are given in the accompanying table.

	Ammonia formed after 30 min. (mgm.)		Ammonia formed after 30 min. (mgm.)
Exp. No. 1.		Exp. No. 3.	
Urease	7·6	Urease	2·1
Urease + ascorbic acid (1 mgm.)..	2 6	Urease + ascorbic acid (1 mgm.) ..	0·0
Urease + dehydroascorbic acid (prepared by Norit oxidation of ascorbic acid)	6·9	Urease + ascorbic acid (1 mgm.) + 8-hydroxyquinoline (2 mgm.) ..	2·0
Exp. No. 2			
Urease	8·3	Urease + ascorbic acid (1 mgm.) + sodiumdiethyldithiocarbamate (2 mgm.)	2·1
Urease + ascorbic acid (1 mgm.)	2·4		
Urease + ascorbic acid +(1 mgm.)+ creatinine (2 mgm.)	4·6		

The results show that the inhibiting action of ascorbic acid is not due to dehydroascorbic acid, as the degree of inhibition exerted by dehydroascorbic acid is negligible compared with that exerted by ascorbic acid at equal concentration. Furthermore, the fact that the inhibition by ascorbic acid can be prevented by substances other than cysteine, which are known to inhibit the oxidation of ascorbic acid by forming complexes with copper[4], tends to show that the inhibition is due to the oxidation of the vitamin by traces of copper present in the reaction mixture. We believe that the function of cysteine also consists in its combination with traces of copper in the reaction mixture, thereby preventing the oxidation of the vitamin.

Our experiments give further support to the view expressed by us[3] that the inhibition of the activity of enzymes by ascorbic acid is associated with the oxidation of the vitamin, and that those compounds which protect the vitamin from oxidation annul the inhibition produced by the vitamin. The inactivation of urease by ascorbic acid undergoing oxidation catalysed by traces of copper may be attributed to intermediate products such as Cu_2O formed during the oxidation.

Further evidence with regard to the mechanism of the reaction will be adduced in the detailed paper to be published elsewhere.

Intracellular Localization of Vitamin C

In a recent communication referring to the use of acid silver nitrate to demonstrate the intracellular localization of vitamin C, Barnett and Fisher[1] state: "It is concluded that it is unjustifiable to infer the whereabouts of ascorbic acid within the cell from the site of silver precipitates obtained by the silver nitrate method". The bases for this statement are the results obtained on the staining of mixtures of gelatin and ascorbic acid and olive oil or ground glass with acid silver nitrate.

The authors have apparently assumed, but have produced no evidence, that the vitamin C in such mixtures is evenly distributed. They feel, therefore, that the presence of granules of silver scattered in the mixture and the deposition of silver granules on the surfaces of oil droplets, pieces of ground glass, etc., is an indication that the granules of silver are deposited independently of the distribution of vitamin C. In the first place, the vitamin might well be distributed unevenly in such mixtures; in particular it might aggregate at surfaces, and, in the absence of proof of its even distribution, this suggestion is as likely to be right as any other. In any event the possibility that some of the granular silver deposits seen in cells after the silver nitrate technique may occur, even if the vitamin C is evenly distributed in cells, was made so long ago as 1933 by me[2], but Barnett and Fisher make no reference to this paper.

The presence of granules of silver in Barnett and Fisher's mixtures is the main basis for the argument that there is not sufficient evidence for the existence of vitamin C in the granular mitochrondria of some organs. They do not adduce important evidence in favour of its presence in these organelles. Thus it has been found[3] that in adjacent frozen sections of the same pieces of tissue stained with Janus green B to demonstrate mitochondria and with acid silver nitrate to demonstrate vitamin C, there was an exact correspondence between the mitochondrial and the silver granules. The organs used for this purpose were adrenal cortex and anterior pituitary. Similar results with the adrenal cortex, the anterior pituitary and the corpus luteum were obtained by Leblond[4] and by Giroud[5]. The latter found the morphology and dimensions of the silver granules the same as those of mitochondria and makes the comment, "Leur disposition correspond entièrement à celle du chondriome". Barnett and Fisher have also omitted to mention the results obtained by ultracentrifugation of cells[6].

Barnett and Fisher state that localization of silver granules in the region of the Golgi material in cells is due to the fact that such granules will in any event tend to aggregate at surfaces. They do not explain why, therefore, in vitamin C preparations, silver granules never aggregate on the surfaces of filamentous mitochondria, but say simply that they present "a different type of interface to that of the Golgi apparatus", as though the Golgi apparatus is surface at which granules of silver will easily aggregate. In fact, Silver[7] has explained the well-known fact that reduced silver will not aggregate on the Golgi surface unless the cell has been first treated with salts of certain heavy metals such as uranium. This paper is not referred to by Barnett and Fisher, yet it is particularly relevant to their discussion. Even if we assumed, for the sake of argument, that the Golgi material presented such a surface, they still need to explain why in the cells of some tissues the

Golgi region accumulates silver granules after treatment with acid silver nitrate, and why in those of other tissues it does not; and why the Golgi material in the cells of the one tissue will accumulate silver granules at one time and not at another; while they do not refer at all to Hirsch's[8] comments on the relation of the staining of the Golgi material of cells with the acetic acid silver nitrate reagent and the production of secretory droplets.

If the results of Barnett and Fisher[1] are significant, one would expect that in organs such as the adrenal cortex and the corpus luteum, where there are large numbers of small fatty and lipoidal droplets in the cells, thus paralleling the oil droplets in their preparations, the application of the acid silver nitrate would cause these droplets to become surrounded with black granules, but in fact it does not. In this organ and in other organs containing fatty droplets, Giroud[5] has stated that he has never seen black granules deposited on the surface of the droplets.

One is forced to conclude that Barnett and Fisher's results quoted above need further support than they have given.

Role of Phosphate in the Methylene Blue Reduction by Dehydroascorbic Acid

WITH reference to the recent publication, by Penney and Zilva[1], on "The Chemical Behaviour of Dehydroascorbic Acid *in vitro* and *in vivo*", I wish to direct attention to my paper "On the Methylene Blue Reducing System of Palestine Orange Peels"[2], the conclusions of which, arrived at by a different method, are supported by the results of the above authors.

While investigating the methylene blue reducing system of orange peels, which was afterwards identified with dehydroascorbic acid (or its irreversible product, diketogulonic acid), it was found that this substance reduced methylene blue, the rate of reduction increasing with increasing pH as from 6·5 to 8·5. But this reaction (which seems to involve the disappearance of diketogulonic acid[3]) proved to be dependent upon the presence of phosphate (which could not be replaced by acetate). I suggested that this explained the discrepancies between Borsook *et al.*[3], who worked with McIlvaine buffer, and Ball[4], who used acetate buffer.

It is interesting to note that Penney and Zilva likewise observed that when they used phosphate buffers (McIlvaine or phosphate-NaOH) "above pH 6, it was found that diketogulonic acid began to decompose, the rate of disappearance increasing with increasing pH", and when they worked with borate buffer, pH 7·4, "the resulting diketogulonic acid was relatively stable and no indophenol-reducing substance was formed from the mutarotating solution".

It is therefore surprising that Penney and Zilva did not note the part played by phosphate, as pointed out in my paper, which is supported by their own experiments, and, as mentioned above, suggests a likely explanation of the discrepancies between Borsook *et al.* and Ball.

Number of Configurations of Molecules Occupying Several Sites

THE number of possible configurations of a mixture of molecules some occupying two sites, the remainder one site, was obtained by Chang[1]. The corresponding number for a mixture of molecules some occupying p sites, the remainder one site, was correctly stated by Miller[2] by analogy, but without proof. By using a technique considerably simpler than that used by these authors, I have been able to generalize these results to a mixture of any number of distinct types of molecules each with its own geometric properties.

Let the molecules of type i be N_i in number; let each such molecule occupy p_i sites; let the number of sites which are neighbours of one site be z; let the number of sites which are neighbours of a molecule of type i be $q_i z$; and let C_i denote the number of distinct configurations of a molecule of type i when one of its elements is fixed on a given site. The p_i's and q_i's are related by $z(p_i - q_i) = 2(p_i - 1)$.

The number of distinguishable arrangements $g(N_i)$ of this system is found to be given by

$$\begin{aligned}\log g(N_i) &= \tfrac{1}{2}z \log (\Sigma_i q_i N_i)\,! - \Sigma_i \log N_i\,! \\ &\quad -(\tfrac{1}{2}z - \;) \log (\Sigma_i p_i N_i)\,! - \Sigma_i N_i \log C_i.\end{aligned}$$

Details of the derivation of this formula and its use to derive thermodynamic properties will be published shortly.

Origin of the Solar System

THE criticisms of Alfvén's theory[1] of the origin of the solar system contained in Lieut.-Colonel Edgeworth's letter[2] seem to be based on a summary of the theory given by its author in an earlier letter[3]. This summary was clearly designed to illustrate the application of the theory to the newly discovered non-solar planetary systems, and it did not bring out what is perhaps the most attractive feature of the theory, namely, that it explains why a large part of the angular momentum of the solar system resides in the outer planets.

In a recent paper[4] Alfvén has shown that a cloud of ionized matter in the neighbourhood of a rotating magnetized conducting sphere is acted upon by electromagnetic forces which tend to make it take

part in the rotation. The sphere becomes electrically polarized due to its rotation, and a system of currents carried by charged particles moving in close spirals around the magnetic lines of force will flow between the ion cloud and the surface of the sphere. The interaction of these currents with the general magnetic field retards the rotation of the sphere and accelerates the cloud. The effect is thus an electromagnetic analogue of viscosity—with this difference, in the case of the solar system: that the mechanical forces involved are large enough to transfer a considerable part of the angular momentum of the sun to the cloud in a time of the order of 10^5 years. This transfer will begin to take place immediately after the ionization described in Alfvén's letter[3], and during the accumulation of the ions near the critical distance, which is identified with the distance of Jupiter. The planets and planetary satellites which afterwards condense from the cloud will, of course, retain the accrued angular momentum after formation.

It is interesting that this hypothesis not only accounts for the distribution of angular momentum among the members of the solar system, but also simultaneously explains the fact that the sun at the present time does not rotate as a whole. The detailed discussion shows that the electromagnetic retardation is greatest at high heliographic latitudes, and it is, of course, well known that the sun rotates more slowly near its poles than at its equator.

Total Colour Blindness of Hysterical Origin

A CAPABLE and energetic motor mechanic and lorry driver aged thirty woke up one morning unable to remember who he was or his recent doings, or to recognize his wife or objects about him.

Before the breakdown he had been totally colour blind: red, yellow, green and blue lights looked white to him. After the breakdown, he was able to name and distinguish some colours of flowers and rug wools. During treatment he was tested at intervals with the Edridge-Green Beads, the Ishihara Test, Stilling's Tables and with the eight Ilford Spectrum Colour Filters and magenta. During six weeks of recovery from the amnesia, his colour vision gradually disappeared again, and he came to see all the colour filters as white, and divided the beads into 'white' (light colours) and 'black' (dark colours). Colours became dazzling and painful to his eyes, although he could not distinguish them. Meantime his normal memories slowly returned.

He was hypnotized by Dr. K. M. Abenheimer and given suggestions that he would be able to see all colours both then and after the trance. Tests during the somnambulic state and after it was over proved him to be an ordinary photerythrous red-green blind. His brother was found to have the same type of colour blindness, and his mother, father and two sisters showed small colour weaknesses.

Under hypnosis he re-lived the scene when he first became afraid of seeing colours. At the age of six he had a sore throat and his mother wrapped a multicoloured scarf round his neck. Later, when lying in his cot, he felt it choking him and cried out to have it removed. After this he had become afraid of the colours in the scarf and lost the ability to see them and all other colours.

He showed a strong emotional identification with his father in many ways, especially in liking hard work, and as a boy he had thought of colour vision as the opposite of his father, who was a coal miner and "could not see colours in the dark". Thus the total colour blindness made him like his father, according to a child's ideas, and saved him from a childish fear of his mother at the same time. It may have been chosen unconsciously as the basis of the child's hysterical reaction against his mother and towards his father because of sensitivity to the existing red-green defect. The amnesia was precipitated by a violent quarrel with a fellow lorry driver who had irritated him by being lazy on a busy day. It was like a childish outburst against his father's influence, and it started a period of amnesia with regression towards his dependence on his mother in early childhood. With this regression his partial colour vision returned, but disappeared again as the regression passed away, and was recovered under hypnosis.

I am indebted to Dr. Angus McNiven, Dr. K. M. Abenheimer and Mr. G. H. Haydock for their help, and to the patient and his wife for their co-operation.

Grassland Improvement

THE Aberystwyth experiments, devised by Sir George Stapledon, on mechanical deep ploughing and reseeding with selected species and strains of grasses, have brought grassland management into line with arable-land experiences and have achieved considerable improvement in ley farming and hill pastures.

Recent exploratory work on rough pasture, moorland[1] and bracken-land[2] has shown that further progress is possible in this direction. The treatment of the area under investigation with calcium cyanamide (10 lb. per rod) and manganous sulphate (4 oz. per rod) during autumn, followed in the spring by reseeding with selected grasses in presence of soil containing nodule bacteria, adds new important features to grassland development. Thus we find that: (1) this method is applicable to areas where a steep gradient or shallow soil based on uneven rock (or clay) makes tillage impracticable; (2) the addition of lime and extensive humification favour the retention of moisture and the formation of a slimy surface, thus making the soil suitable for reseeding without ploughing; (3) calcium and nitrogen are added in a form and quantity corresponding to a long- and short-term fertilizer, benefiting both light and heavy soil (with the introduction of phosphorus and potassium when necessary); (4) parasiticidal activity and rapid humification add considerably to the fertility of the soil by their combined action upon the flora and fauna; (5) during this treatment the nitrogen-fixing and nitrifying bacteria are regenerated. Nitrification, nitrate and trace element (Cu) assimilation are also catalysed by the manganous sulphate[3], which as an anti-chlorotic agent[4] participates in the chlorophyll metabolism, and (6) the loss of nitrogen, accompanying the nitrous acid reactions in the soil, is greatly reduced by the carbohydrates abundant in the humifying bracken rhizomes[5].

The development of the Highland hydro-electric

scheme should make calcium cyanamide readily available in Great Britain, and the destructive action of this material upon parasites, ranging from viruses and fungi to wireworms, leather jackets, etc., should provide an important problem for parasitology.

Origin of Indo-European Languages

PROF. ALEXANDER JÓHANNESSON, whose article appeared in NATURE of February 5, is, I believe, the first philologist of high academic standing who has systematically studied the sounds of speech from the point of view of the gestures of articulation which produce them, and has thus discovered for himself the pantomimic structure of human speech. His conclusions coincide generally with my own, which were originally drawn from the acoustic study of speech sounds.

There are, however, a few items in Prof. Jóhannesson's statement which seem open to question. He considers the Indo-European *R* sound as "originally cacuminal, hard and vibrating". I would have suggested that the Indo-European *R* was more probably produced by a backward curvature of the tongue tip, so as to produce a sound like the Wessex 'burr'. Its pantomimic meaning would be to bend or bend back, surround, cover, draw back, as in rake (heap up), ramp, rape, rim, ring, rend, ream, rib, reef, reel, rest, roost, rick, ride, rig (bind), rob, roll, roof, room, rope, round, rug, rump.

As to the vowels: *E* (as in men) is the result of a mid-height tongue posture; the pointing at oneself in ego is, I suggest, due to the *EG* gesture. I do not think that *EU* represents a 'circulating movement'; it is rather a forward movement (*U*) at mid-height (*E*).

Prof. Jóhannesson considers *S* as primarily an imitation of sounds in Nature. I would suggest that the *S* gesture generally denotes extension to a fine point or edge or limit. Thus, *SK* denotes extension from a forward point (*S*) to a backward point of closure (*K*); hence, skin, skim, skein, skid, scalp, skull (with hollow *U*), scoop. *SL* denotes sliding back or down: for example, slant, slip, slide, sleek, sleep, slope, slum, slump. *SM* denotes a sliding action towards a forward (lip) closure *M*, as in smear, small, smooth. *SN* is an in-drawing gesture, commonly associated with in-breathing through the nostrils, as in sneeze, snore, snout; or an inward or upward movement, as in snug, snag (projecting point). *SP* denotes drawing to a terminal point or fine edge, as in spear, spire, spout, spit, spade, spoon, spur, and asp, wasp, wisp. *STR* represents an elongated fore and aft movement, as in strong (extended hand drawn up towards the shoulder and terminating with a clenching of the fist), straight, stream, string, strand, strake (of timber), stretch, etc. *SW* is a forward motion, as in swell, swim, swift, swirl, swoop, swoon.

As to the symbolism of abstract ideas, I would suggest that in speech—as in sign language—the original meanings of all gestures have been concrete, and that the corresponding abstract interpretations have come later. It was the poetical faculty in man that enabled him to express his hitherto inexpressible sensations by concrete gestures, so that a shrinking gesture such as that of fear, fright, could be used to express the inclination to shrink, or the full-mouthed gesture 'good' to represent anything that was felt to be satisfying.

R. A. S. PAGET.

Cranmore Hall, Shepton Mallet, Somerset.

Two of Prof. Jóhannesson's works—his "Grammatik der urnordischen Runeninschriften" and his "Islenzk tunga í fornöld"—are well-established handbooks for the Germanic philologist. But, in his recent article in NATURE[1] (and more fully in the Icelandic work to which he there refers), he has embarked for more unconventional regions. There is, in fact, no doubt that Prof. Jóhannesson has contravened that ancient and famous minute of the Société de Linguistique which prohibited discussion of the origin of language. There was—and always will be—a sound basis for that excellent minute, and for a simple reason. In all languages known to us—whether ancient (like Sumerian) or modern (like modern English)—we observe that, for the great majority of words, the connexion between sound and sense is random; thus there is no reason known to us why, in English, the word for "7" should begin with *s* and that for "10" with *t* rather than vice versa. We may suppose that, in the very distant epoch when language originated, either the sound-sense relation was random or it was not. But the linguistic changes which must have operated in the long period intervening would certainly have quickly reduced a non-random sound-sense relation to a random one, similar to that which we have in known languages.

Therefore to accept Prof. Jóhannesson's theory is to disbelieve in the heterogenizing effect of continuous linguistic change, and to do this would be to go against all that we know of language. There is implicit in Prof. Jóhannesson's views the suggestion that reconstructed Indo-European preserves an original non-random sound-sense relationship (cf. his remark in para. 4: "The roots beginning with dentals have a similar meaning, as the first man either pressed his teeth together . . ."). Reconstructed Indo-European is usually attributed to the third millennium B.C. and was presumably the language of a people at a fairly high level of civilization; thus long vistas of masking sound-change must separate its dentals from the original state of affairs envisaged by Prof. Jóhannesson.

Two special points call for comment. In his third paragraph Prof. Jóhannesson offers some discussion of ablaut; it is, at the least, remiss of him not to have taken cognizance of the views of Kuryłowicz, who succeeded, in the years before the War, in tracing the history of the Indo-European vowels to an earlier stage than had been reached up to that time. On p. 172 Prof. Jóhannesson says that "Philology must become a scientific study". To most philologists the question whether philology is a science or an art will scarcely seem important, but admirers of the great masters of scientific philology—Brugmann, de Saussure and, above all, Meillet—will find it hard to condone the implication that these men were at fault in their method.

RESEARCH ITEMS

Transfusion into the Bone Marrow

WORKERS who are studying the intravenous administration of blood and other fluids will be interested in the method of delivering such parenteral fluids into the manubrium of the sternum which is described by Mr. Hamilton Bailey, of the Royal Northern Hospital, London (*Brit. Med. J.*, 181; Feb. 5, 1944). Referring to the work of L. M. Tocantins and J. F. O'Neill (*Surg. Gynæc. Obstetr.*, 73, 281; 1941), Mr. Bailey says that he considers the manubrium as good a receptor as a vein for infusions of all kinds and for pentothal anæsthesia. After local anæsthesia with novocain, a special trochar is introduced between the two plates of the manubrium, the depth to which it penetrates being controlled by two wings on the instrument. To make sure that the bone marrow has been reached and to avoid such possible accidents as the injection of the fluids into the superior mediastinum, sodium citrate is first injected with a syringe fixed to the cannula. If this syringe then withdraws bone marrow, which looks like blood, easily and liberally, it is known that the cannula is in the bone marrow. It is then quickly linked to the transfusion apparatus. A possible danger is the production of osteomyelitis, but this has not occurred in Mr. Bailey's sixty cases. Whole blood cannot be introduced as rapidly as it can be given into a vein by gravity, but this difficulty is being overcome. Advantages of the method are that it is relatively painless, that thrombosis or phlebitis cannot occur, and that the apparatus is on the sternum and so is out of the way of the surgeon during operations and can be controlled by the anæsthetist. The method is also free from the difficulty, which is often considerable, of getting a cannula into the veins of severely shocked patients, whose veins may be also so severely collapsed that satisfactory reception of the parenteral fluid is difficult; in dehydrated infants the method is certain and safe. It can, moreover, be carried out in a poor light, so that fluids can be given more easily and quickly under black-out conditions.

Inheritance of Awn Barbing in Wheat

THE beards or awns of wheats are normally rough, due to short, thick-walled, unicellular hairs with fine points which are directed towards the tip. Among 'smooth'-awned durum wheat selections, it has been found that two different, true-breeding types may be distinguished (P. F. Knowles, *Canad. J. Res.*, 21, C 198; 1943). In the first type, termed 'smooth', the upper half of the awn is free from barbs and the lower half very slightly scabrous, increasing in intensity towards the base of the awn. In the second or 'intermediate' type, barbs are found from the tip to the base of the awn, but in the upper part they are few in number and reduced in size, whereas in the lower portion they are very numerous and intermediate in character between the 'smooth' and the normal 'rough' types. The types are shown to be due to the expression of two pairs of alleles, designated *Rr* and *Ss*. *RRSS*, *RRSs*, *RrSs*, *Rrss*, etc., are 'rough'-awned, *rrSS* is 'intermediate', *rrSs* is a non-true breeding 'near-smooth' and *rrss* is the true-breeding 'smooth'-awned type. The segregations obtained for the characters of glume colour, glume pubescence and awn colour, showed that the inheritance of each is determined by the action of one pair of factors, that glume pubescence is linked with awn colour and that the inheritance of all these is independent of awn barbing. It is a pity that the symbols R and S have been used in accordance with the notation first used for barley but now discarded for that species: R is usually reserved for the three grain-colour factors and S has been used for the spring habit. Furthermore, the smooth-awned gene originally designated S in barley is a dominant.

Physiology of Incompatibility in Plants

IN the third paper of this series, D. Lewis (*J. Genetics*, 45, 171; 1943) describes his investigations on incompatibility in autotetraploids. It will be remembered that in diploids a style carrying S_AS_B will inhibit the growth of either S_A or S_B pollen grains. In tetraploids there are complications such as the pollination of $S_AS_CS_CS_D$ by S_AS_B pollen. Using synthesized tetraploids of *Œnothera organensis*, the author has investigated this and similar phenomena. Pollen heterozygous for different S factors can be shown to differ by their reaction to temperature and growth. The fact that a pollen tube carrying an incompatible and a compatible gene in relation to those of the style show different reactions according to the specific genes involved indicates that competition is taking place for some substance. The author suggests the similarity between incompatibility in plants and the phenomena of antigens and antibodies in animals. The effects of incompatibility upon survival of tetraploids and economic selection are discussed.

Effects of Banana Selection

K. G. DODDS (*J. Genetics*, 45, 113; 1943) has examined the cytology of some diploid parthenocarpic bananas. Three of the five examined are structural hybrids, a fourth shows little bivalent formation while the fifth exhibits a single reciprocal translocation. Parthenocarpy and sterility of the female flowers is genetic in origin. The author shows that parthenocarpy and female sterility arose by gene-mutants in fertile diploids; the resulting edible types were taken into cultivation and propagated by clones. By selection, and in course of time, parthenocarpy became established, and with the absence of selective control on the sexual process the evolution of structural hybridity took place. This was favoured probably by the selection of more sterile forms. Hence male sterility was added to female sterility. Later, polyploidy arose, but this is considered to be of less importance in the evolution. Possibly the larger size of polyploids may have attracted the early selectors.

Electric Polarizations in Extremely Dilute Solutions

THE abnormal behaviour sometimes found in the polarization curves at high dilutions on plotting polarizations against mol fractions has been supported by some investigators and denied by others. R. Davis, H. S. Bridge and W. J. Svirbely (*J. Amer. Chem. Soc.*, 65, 857; 1943) have made some measurements in benzene and dioxane solutions and computed the molecular polarizations by Hoecker's method. This involves plotting the product of polarization and mol fraction of the solute P_2N_2 against N_2 and taking the slope of the resulting line as P_∞. This will be equal to P_∞ only if P_2 is constant. Large-scale plots showed that the P_2N_2 against N_2 plot was linear under proper conditions, and the conclusion was reached that the

abnormal behaviour in polarization curves encountered in very dilute solutions is due to experimental error in measuring P_1 and has no physical significance.

Solubility of Silver in Mercury

AN interesting study of the solubility of silver in mercury has been published by D. R. Hudson (*Metallurgia*, Sept. 1943). The author has determined the solubility over a range of temperatures up to 450° C., the materials being sealed in a glass bulb. The measurements, combined with those of previous workers, with which they are consistent, afford information extending over a temperature range exceeding 950° C. Measurements quoted in the highest range up to the melting point of silver were made by Murphy using the usual metallurgical methods. The existence of the peritectic temperatures of formation of Ag_5Hg_4 and Ag_5Hg_8 produces no noticeable effects on the graph of log N_{Ag} plotted against $1/T$ (where N_{Ag} represents the molecular fraction of silver in the saturated liquid solution, and T represents the absolute temperature). At two other temperatures, however, sudden changes of slope of the graph occur, and may be roughly predicted from purely physical properties of silver and mercury by using an equation due to Hildebrand. The equation may be modified so as to allow for the solid solubility of mercury in silver, and in this way a somewhat closer approximation to the experimental determinations can be obtained. Although the equations used by Dr. Hudson exhibit the main features of the experimental determinations, the shape of the liquidus curve of a binary metallic system cannot in general be closely predicted from a knowledge of relevant physical properties of the pure components.

Carbon Monoxide 'Cool Flame'

AT a temperature just below the ignition point, a mixture of carbon monoxide and oxygen shows a pre-ignition glow or 'cool flame', the spectrum of which has been studied by A. G. Gaydon (*Proc. Roy. Soc.*, A, 182, 199; 1943). Photographs were got of the spectra with carbon monoxide and oxygen or nitrous oxide. The cool flame shows the same faintly banded spectrum as the normal flame. but this band structure is more clearly developed. The OH bands are absent from the cool flame, which, however, shows strong sodium emission. Cuprous chloride appears very readily as an impurity, and the band systems of CuCl show a markedly different intensity distribution in the cool flames with oxygen and with nitrous oxide. The application of the results to the theory of the combustion mechanism is briefly discussed. The paper is the third in a series on the flame spectrum of carbon monoxide.

Electron Diffraction of Amorphous Polymers

WHEREAS some polymeric substances give characteristic crystalline diagrams under X-ray or electron diffraction examination, others show such diagrams only when stretched under suitable conditions of temperature. Normally, in their unstretched form they give an 'amorphous' pattern, retained in several cases even on stretching. Special attention has been given to 'amorphous' polymers by G. D. Coumoulos (*Proc. Roy. Soc.*, A, **182**, 166; 1943). The configurations of polyvinyl acetate and the acrylate and methacrylate polymers revealed by electron photographs suggest a zigzag carbon atom chain for the long main-chain, which has the 1,3 structure, with the side-chains alternately on the right and the left of the zigzag chains and on planes approximately perpendicular to the axis of the main chain. These side-chains are subject to lateral cohesive forces which group them in clusters. In the clusters, the side-chains tend to lie parallel to one another. In the lenses the clusters consist of a few side-chains showing no recognizable arrangement. The multi-layer pattern suggests a certain orientation of the side-chains with perhaps more grouping together. The patterns indicate an 'amorphous' character due to the close packing of the side-chains in clusters, producing distortion of the main-chain and preventing adlineation. On the basis of this configuration, some of the elastic properties of these polymers are discussed and a note is made on the occurrence of high elasticity.

Production of Penetrating Showers

L. Jánossy and G. D. Rochester have reported (*Proc. Roy. Soc.*, A, 182, 180; 1943) the results of an experimental study of the nature of the shower-producing radiation suggested by an earlier investigation by Jánossy. It is shown that about one third of the radiation producing penetrating showers is non-ionized and more penetrating than photons. The total intensity of this non-ionizing radiation, named N-radiation, is found to be about 0·001 per cent of the full cosmic radiation near sea-level. The N-radiation is possibly the energetic part of the penetrating non-ionizing component of cosmic radiation. It is suggested that this radiation consists of neutrons.

Direction of Rotation in Spiral Nebulæ

UNAMBIGUOUS determination of the direction of rotation of extra-galactic nebulæ with respect to their spiral pattern needs three data: the sense of the rotation, the sense of the spiral pattern and the sense of the tilt. The first can be obtained from spectrograms, the second from direct photographs, but there is still considerable controversy over the determination of tilt, which cannot be observed directly but must be inferred from observations which may be interpreted differently by different people. A recent paper by Edwin Hubble (*Astrophys. J.*, 97, 112; 1943) uses dissymmetry of obscuration with respect to the major axis as a criterion of tilt in fifteen spirals in which the arms can be traced. He finds that the arms are either all trailing or all leading the nuclei. In four critical cases, he claims, lanes of obscuration silhouetted against the nucleus show unambiguously which is the nearer side of the nebula; and applying this criterion of tilt, he finds that the arms are trailing. As a working hypothesis he therefore assumes that the arms trail in all spirals. In recent papers, however (*Stockholm Ann.*, **14**, Nos. 1, 3, 4; 1942), Lindblad and Ohman come to the opposite conclusion by assuming that the dark matter is distributed more or less uniformly through the nuclear region. The heavier obscuration should then occur on the farther side of the nucleus, where the light rays are absorbed most. Unfortunately, in the one case where the Swedish school agrees with the American as regards the direction of tilt, they disagree on the sense of the spiral pattern. The matter is of great importance in discussing the evolution of spiral nebulæ, and further independent evidence is badly needed.

CHEMICAL STRUCTURE AND ANTI-FIBROMATOGENIC ACTIVITY OF STEROID HORMONES

By Dr. ALEXANDER LIPSCHÜTZ

Department of Experimental Medicine, National Health Service of Chile, Santiago

LIPSCHÜTZ and Iglesias[1] showed that subserous fibroids scattered in the abdominal cavity (gastric, splenic, mesenteric, uterine, parametric and fibroids of the abdominal wall) can be induced in female guinea pigs to which œstrogens have been administered for a sufficient length of time. These fibroids infiltrate into surrounding tissues, especially smooth and striated muscle. All œstrogens, natural or artificial, free or esterified, have been found to be fibromatogenic. Localization of these abdominal fibroids follows a certain pattern independent of the œstrogen used[2] (for summary, see ref. 3). In the course of our work we have also established that certain steroid hormones, when administered simultaneously with the fibromatogenic œstrogen, prevent formation of fibroids. Progesterone, desoxycorticosterone[4], dehydrocorticosterone[5] and testosterone[4] were shown to be antifibromatogenic. Fibroids which have already been induced by œstrogenic action begin to regress when about three months later an antifibromatogenic steroid (progesterone) is given and allowed to act simultaneously with the œstrogen[6,7].

All the four natural antifibromatogenic steroids mentioned were 3-keto-steroids with a double bond Δ^4 in ring I. Progesterone and seemingly also desoxycorticosterone were more active than testosterone, and it was assumed that the side chain of two carbons at C_{17} enhances antifibromatogenic action[8,9,10]. On the basis of these findings and assumptions, a systematic search for antifibromatogenic steroids was made among known artificial steroids with the purpose of relating antifibromatogenic activity with chemical structure. So far, a total of ten different artificial steroids, that is, steroids not occurring in the body, and some esters of these have been studied[11]. The results are summarized in the accompanying table.

Three artificial 3-keto-steroids were tried. Δ^{16}-dehydroprogesterone, which differs from progesterone by a double bond in ring IV, showed no antifibromatogenic power even when considerable quantities were used. The antifibromatogenic activity of testosterone is abolished by oxidation at C_{17}; Δ^4-androstene-3-17-dione failed to prevent fibroids even when huge quantities were absorbed. Prolongation of the side chain in position 17 also was detrimental: cholestenone was not antifibromatogenic.

Dihydrotestosterone lacking the double bond Δ^4 was found to be no less active than testosterone. On the basis of this finding, two compounds lacking the double bond Δ^4 but having the side chain at C_{17} like progesterone were tried; but both these artificial steroids, allo-pregnanedione prepared by Dr. K. Miescher from cholesterol and pregnanedione prepared by Dr. A. S. Cook from urine, were found to have no antifibromatogenic faculty.

All steroids, natural or artificial, having a hydroxyl group at C_3 failed to show antifibromatogenic activity, whether the side chain of two carbons at C_{17} was present (acetoxypregnenolone, substance *H* of Kendall) or not (androsterone, androstanediol, androstenediol).

As to the relation of antifibromatogenic action to the *physiological* activities of steroid compounds, the following statements can be made. All 3-keto-steroids which we found to be antifibromatogenic are known to be *progestational*, though in a varying degree; but all 3-keto-steroids which were found not to be antifibromatogenic, are not known to be progestational, with the possible exception of androstenedione. *Masculinizing* activity is not concomitant with the antifibromatogenic one, as shown by two different facts: there was no masculinization of the genital region in the guinea pig (transformation of the clitoris into a hypospadic penis) with antifibromatogenic quantities of progesterone, desoxycorticosterone and dehydrocorticosterone, whereas masculinizing quantities of androstenedione were not antifibromatogenic. Neither was there full parallelism between antifibromatogenic and *antiœstrogenic* activities. Though the vaginal opening closed often definitely under the influence of antifibromatogenic steroids, proliferation of the basal epithelium of the vaginal mucosa was not fully inhibited. The growth of the nipples and of the mammary glands was not inhibited but rather enhanced by antifibromatogenic steroids.

The statements referring to the correlation of the antifibromatogenic activity of steroids with their chemical structure and with certain physiological activities, conflicting as these statements are so far, may serve as important starting points for further experimental work in the field of research on antitumoral actions of steroid compounds, natural or artificial.

Our work with tumorigenic and antitumorigenic steroids was aided by grants from the Rockefeller Foundation and the Jane Coffin Childs Memorial Fund for Medical Research. It was greatly furthered by the application of the ingenious technique of subcutaneous implantation of steroid tablets advised by Drs. R. Deanesly and A. S. Parkes[12]. Thanks are due for steroids to Dr. E. C. Kendall of the

THE PULSATION THEORY OF CEPHEID VARIABLES

PROF. SVEIN ROSSELAND delivered the George Darwin Lecture of the Royal Astronomical Society, on September 10, 1943, on "The Pulsation Theory of Cepheid Variables", and the address is now available (*Mon. Not. Roy. Astro. Soc.*, 103, 5; 1943).

In the introduction, Prof. Rosseland refers to different types of stellar motions, the simplest type of large-scale motion being rotation round a fixed axis; this particular problem must be considered to be still in a preliminary stage both from the theoretical and observational points of view. The expansion and contraction of a star as a whole is a second type of large-scale motion, and this can be said to be represented in the sun by the outward motion of the corona; but it is most conspicuous in Wolf-Rayet stars and novæ, where direct observation of the expansion is possible. In the case of Cepheids and other periodic variable stars, it is believed that a *periodic* type of expansion and contraction is at the root of the phenomena.

The problem of interpreting the behaviour of Cepheid variables was responsible for the idea that stars may perform spherical pulsations, and it is interesting to notice that Coodricke, who announced the variability of δ Cephei in 1783, was cautious enough not to attribute its variability to eclipses in a binary system, like β Persei. It was not until 1879 that August Ritter developed a rudimentary theory of the pulsation hypothesis and suggested that Cepheids might owe their light-variation to pulsation. He made the important discovery that the slowest mode of pulsation of a homogeneous star has a period inversely proportional to the square root of its density, and also found that this mode of pulsation becomes unstable when the ratio of specific heats falls below 4/3—a result which holds, not only for the Cepheids, but for other gaseous stars as well. Unfortunately, Ritter's suggestion received little attention, and in 1894, when Belopolsky discovered the periodic variation in the position of the lines in the spectrum of δ Cephei, this fact was interpreted as a confirmation of the binary star theory of Cepheids.

Plummer was the first to show that the binary hypothesis was very doubtful, and in the following year, 1914, Shapley ruled out the hypothesis by an analysis of observational data, suggesting the pulsation hypothesis as an alternative. His most convincing argument was that if a companion to a Cepheid were responsible for the light-variation, the size of the orbit would be so small that the companion would necessarily move well inside its primary. Eddington took up the subject of the pulsating hypothesis in 1917–18 and raised it to the rank of a mathematical theory in which quantitative issues are involved. A few observational facts about Cepheids were definitely established by that time; thus the periods, the general form of the light-curve, the velocity-curve, and the period-luminosity relation were known. More information is now available on the correlation between the period and the mean density, enabling a preliminary check to be made on the theoretical law, and in addition, much more material can be utilized concerning the form of the light- and velocity-curves.

The problem of the pulsation theory is beset with many difficulties, and it has been found necessary to approach it in successive steps. In the first step, the theory was developed within the framework of ordinary acoustics, and in this case wave motions are linearly superposed to form compound waves, the oscillations being assumed adiabatic. Within the acoustic limit the relation

$$P\sqrt{\rho} = K$$

holds, where P is the period and ρ the mean density, K being a constant for each stellar model, but differing for different models. When $\log P$ is plotted against $\log \rho$, the plot should reduce to a straight line forming an angle of 45° with the axis, for stars of the same model, and stars of the short-period and Cepheid type fall very closely along a line which is parallel to this line, but well to the right of it, thus confirming theoretical expectations. The long-period stars fall widely off the line, still farther to the right, and the only group that conforms to expectations is the small group of short-period variables in Messier 3, discovered by Schwarzschild. Two possible ways of overcoming the difficulty are suggested. If it is admitted that different groups of stars have different values of the ratio of specific heats, a drop from 1·6 to 1·4 would suffice to bring the theoretical line into coincidence with the observed Cepheid line, but a considerably greater alteration would be necessary to bring the theoretical line into coincidence with the observed long-period line. No physical basis exists for such an assumption regarding the alteration in the specific heats ratio. Another suggestion is that the stellar model should be altered so that the central density would be 10 times instead of 54 times the mean density, but even such a drastic alteration would not explain the position of the long-period variables in the diagram.

After discussing these difficulties, Prof. Rosseland deals with his own work, in which the acoustic approximation is abandoned. In the case of an ordinary pendulum, infinitely small oscillations are sinusoidal, and the period is independent of the amplitude, like small oscillations of a star. When the swings of a pendulum increase, the oscillations cease to be sinuosidal and are represented by elliptic functions, the period increasing at the same time. If a curve is plotted giving velocity against time, the change in its shape enables us to infer the length of the period, and we might expect, in a general way, that the

same situation holds for the pulsations of a star. As the velocity curve differs more and more from a simple sine curve, so the period may be expected to lengthen relative to the period computed from the elementary theory. Eddington dealt with the subject of an extended pulsation theory in 1918, and showed that theory predicts a faster rise of the velocity to a maximum than the subsequent drop to a minimum, and in 1937 Miss Kluyver extended the investigation to include a dependence of period on amplitude. Prof. Rosseland develops his theory of 'anharmonic pulsations' in an appendix, and finds that the semi-amplitude of oscillation would have to be a quarter of the radius of the star—a value 4–5 times too great for most of the Cepheids. He admits that there is a considerable discrepancy to bridge, and it does not appear that this can be done by varying the model. It can probably be done if the calculations are extended to include more coupling terms in the equations.

In conclusion, Prof. Rosseland points out the incompleteness of the pulsation theory in its present stage, and even the 'anharmonic theory' must still be considered to be in its infancy. As already pointed out earlier in this summary, there is a problem connected with the separation of the Cepheids, long-period variables and the $M3$ group, and no solution has yet been attained. It is suggested that inherent physical differences between the stars of these three groups exist. Regarding the phase retardation of luminosity, the pulsation theory has little to say, though it is admitted that Eddington's suggestion about the hydrogen convection zone may finally lead to a solution of this problem. In this connexion further work on the anharmonic pulsations may be important, and the same applies to the period-luminosity law, an interpretation of which has not yet been afforded. The fact that the pulsation theory has survived for nearly thirty years against hard tests is an indication of the soundness of its basic assumptions, and it will remain a fruitful field of work in the future development of astrophysics.

NATIONAL RESEARCH COUNCIL OF CANADA

THE annual report of the National Research Council of Canada*, 1941–42, includes the report of the president, the financial statement for the fiscal year 1941–42, as well as the reports of the directors of the various divisions, the Gauge Measurement Laboratory, the Radio Board, the Section on Codes and Specifications and the Research Plans and Publications Section. Practically all the activities of the National Research Council in 1941 were directed to the study and solution of problems immediately connected with Canada's growing war effort, and the Council has been officially designated as the Research Station of the Royal Canadian Navy, the Army and the Air Force, and is shown as a civil establishment in the records of the Department of National Defence.

The Divisions of Chemistry and of Applied Biology have been engaged largely in selecting and testing suitable materials for the use of the armed forces, and in the Physics, Electrical and Mechanical Engineering Departments, the design and development of new detecting devices to locate aircraft, submarines, mines, and other enemy equipment have been carried forward with much success. Engines, aircraft and other items of equipment used in mechanized warfare have been tested on a large scale, and additional staff and facilities have been provided to meet the new requirements, the staff of the Council working in the Ottawa area numbering 803 on March 31, 1942, as against 308 in July 1939, the greatest increase in numbers being in the Division of Physics and Electrical Engineering. New buildings have been constructed to house the aeronautical and hydraulic laboratories and the work of some of the other divisions. A radio field station has been established near Ottawa, and owing to the large increase in the staff of the radio section, a Radio Board has been established for the general direction of all radio research and development work in connexion with the Council's war activities. An important war service has been rendered by promoting the development in Canada of optical glass manufacture for precise optical parts of military equipment.

The Division of Biology and Agriculture, which has been renamed the Division of Applied Biology, has devised methods for converting large insulated cargo holds into refrigerating space without delaying the vessel to provide an immediate solution for the acute bacon transport problem, and a standard curing practice has been developed in Canadian package plants which yields a more stable product. Other work in progress in this Division relates to the treatment of shell eggs to prevent deterioration during shipment at ordinary temperatures, tests on the quality of dried eggs and the preparation of specifications for shipping, investigations on drying pork, canning poultry, vitamin content of flour and the development of rapid growing, easily propagated forest trees; vegetative propagation has reached the stage when cuttings of Norway spruce, white spruce and white pine can be successfully rooted on a practical scale.

In the Division of Chemistry, the Plastics Laboratory of the Colloidal Section, which was being equipped at the outbreak of war, has carried out a survey and experimental work on the use of laminated wood in aircraft construction in co-operation with the Division of Mechanical Engineering. In the physical chemistry section investigations on the development of de-icing fluids, prevention of frost deposition on aircraft, resolution of aerial photographs, etc., have continued, while the organic chemistry section has continued its general programme of research on alkaloids and has synthesized indicators for war gases and chemicals for other war purposes; in the preparation of some special organic chemicals, production has been advanced to semi-pilot plant scale. In addition to investigating products used by almost every branch of the armed forces, including surgeons' gloves, ground sheets, gas-mask components, etc., the rubber laboratory has given much attention to rubber conservation problems and to the study of processes for synthetic rubbers. The refractories laboratory continued its investigations of high-temperature furnace linings. Experiments on the production of metallic magnesium have been pushed forward until a process worked out in the laboratory has been sponsored in a more detailed study embodying pilot-plant operation by a group of industrialists.

Activities in the textile laboratory were largely devoted to acceptance test work and specifications. An explosives laboratory was established late in 1941 to carry out testing under the Explosives Act and conduct research on explosives and related compounds.

* Twenty-fifth Annual Report of the National Research Council of Canada, 1941–42. (N.R.C. No. 1089.) Pp. 33. (Ottawa.)

Under war-time conditions, the demand for searches of scientific literature in planning laboratory research have increased; research workers in all fields of science have made increasing demands on the trained personnel of the Council staff who prepare bibliographies and abstracts or digests of the literature. Although ten of the Council's numerous associate committees have been disbanded and others will remain inactive until after the War, many new committees have been established to give advice or organize and direct research on important problems, in addition to the twenty-eight associate committees of the Council in existence at the end of the year. Special reference is made in the report to the associate committees on medical research and on aviation medical research. Subjects selected for investigation by these sub-committees have included problems in fatigue, vision, hearing and related subjects, wound infection studies, including work in chemotherapy, treatment of shock, development and provision of blood substitutes for transfusion purposes, treatment of burns and other war injuries, dietary studies, problems involved in high-altitude flying and the improvement of oxygen breathing-systems, and protective clothing to counteract effects of cold, fatigue and high accelerations.

The Council has also been particularly active in maintaining the most effective liaison possible in the scientific work going on in Great Britain, Canada and the United States.

SEAWEED PRODUCTS IN AUSTRALIA

By E. J. FERGUSON WOOD and VALERIE MAY JONES

Fisheries Div., Council for Scientific and Industrial Research, Australia

PRIOR to 1940, little had been done in Australia to develop any industries using seaweeds as the raw material. In the last century, a company was formed to make agar from the red alga, *Eucheuma speciosum* (Sond), J.Ag. at Dongarra in Western Australia; potash was produced from Macrocystis and Ecklonia in Tasmania during the War of 1914–18, and several attempts were made at different times to utilize the fibres of *Posidonia australia* Hook. F., which is prolific in South Australian waters and elsewhere. With the death of each of these schemes, seaweed research for industrial purposes languished, and even taxonomy was so neglected that for some years prior to his death, A. H. S. Lucas was the only person in Australia working with the marine algæ of the Continent.

The need for agar in Australia stimulated seaweed research, and the discovery of a quantity of *Gracilaria confervoides* (L.) Grev. at Bateman's Bay and Botany Bay in New South Wales revived interest in the Rhodophyceæ. Studies on the method of production of agar from Gracilaria, carried out at the laboratory of the Fisheries Division of the Council for Scientific and Industrial Research, have culminated in the undertaking of agar production by a Sydney firm. *Gracilaria confervoides* is known to occur in large beds in shallow water in a number of areas in New South Wales and southern Queensland, and is very easily harvested and dried. It is estimated that there will be sufficient raw material in New South Wales to produce at least 100 tons of agar per year, even allowing for fluctuations in the growth of the seaweed. Gracilaria has been found along the coast from Tuross Lake in New South Wales to Urangan in Queensland, a distance of 850 miles. It occurs on shallow flats, in lagoons, estuaries and bays, where conditions are favourable. There is a seasonal rhythm in its abundance, though it appears that this may vary in some seasons. The spores appear to adhere often to shellfish (usually whelks, sometimes cockles and mussels) or to a polychæte worm cast (Eunice), and occasionally to sticks, rocks, etc. Experiments are being made with a view to the cultivation of Gracilaria.

The seaweed is harvested by special grapnels or, in very shallow water, by hand, then loaded into dinghies and taken ashore and dried on wire-netting racks. When dry, it is pressed into bales, and is ready for the manufacturer.

The cardinal features of manufacture are boiling with live steam in open vats, and keeping the pH below 7 and preferably below 6·5, but above 5·0. Owing to the difficulty of procuring the necessary materials, the agar has been made in iron or copper equipment, and this results in discoloration and in a high ash residue. Efforts are being made to overcome this. Gracilaria agar tends to be viscous and to have a high setting point, but these are no detriment in the food industries. For bacteriological purposes, Jensen has shown that although these qualities are a disadvantage for poured plates, slopes made from Gracilaria agar will grow most organisms as well as, if not better than, the slopes made from Japanese agar. Two British bacteriologists have also expressed satisfaction with Gracilaria agar in private communications to one of us.

Agar is also manufactured in Western Australia from *Eucheuma speciosum*, which appears to grow in quantity on reefs in the Dongarra district, and to some extent elsewhere. Detailed surveys of these beds are projected. The agar is more easily extracted from Eucheuma than from Gracilaria, but collection of the seaweed from reefs will prove more difficult. This agar also is used for meat canning, and has the same disadvantages for bacteriological purposes as Gracilaria agar.

Hypnea musciformis (Wulf) Lam. is moderately widespread in occurrence, though not occurring in large quantities in any one part of Australia. It makes a very good bacteriological agar with a low viscosity and setting point. It is not used commercially so far.

At the present time, Australian agar production is far below local requirements, but there appears to be no technical reason why these requirements should not be met within the next twelve months, and there is every indication that the raw material will prove adequate.

The production of alginates, potash and iodine have been studied also, and alginates of excellent quality can be prepared from Ecklonia from New South Wales, or from Macrocystis from Tasmania. Abundant growth of Macrocystis occurs in southern Tasmania, which would be the logical centre of the industry. Unless produced as a sideline from an alginate plant, potash and iodine production could be made payable only in war-time. No commercial production of these substances has yet begun.

The commercial development of agar has stimulated systematic and distributional studies of the Rhodophyceæ, and this work is progressing steadily.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public.)*

Saturday, February 26

SCHOOL NATURE STUDY UNION (at the Central Club, Y.W.C.A., Great Russell Street, London, W.C.1), at 2.30 p.m.—Thirty-eighth Annual Conference; at 3 p.m.—Prof. W. B. R. King: "The Evidence of Fossils".

Monday, February 28

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Dr. E. B. Bailey, F.R.S.: "Natural Resources of Great Britain", 2: "Underground Water". (Cantor Lectures, 2.)

SOCIETY OF CHEMICAL INDUSTRY (PLASTICS GROUP) (joint meeting with the ASSOCIATION OF TAR DISTILLERS) (at Gas Industry House, 1 Grosvenor Place, London, S.W.1), at 2.30 p.m.—Dr. H. Levinstein and Mr. J. Idris Jones: "Plastics and the Coal-Tar Industry".

BRITISH ASSOCIATION OF CHEMISTS (NORTH-EAST SECTION) (in the Chemistry Lecture Theatre, King's College, Newcastle-upon-Tyne), at 5.30 p.m.—Prof. J. B. Speakman: "Protein Fibres, their Reactivity and Industrial Application" (Fifty-fourth Bedson Lecture).

ASSOCIATION OF AUSTRIAN ENGINEERS, CHEMISTS AND SCIENTIFIC WORKERS IN GREAT BRITAIN (at Austria House, 28 Bryanston Square, London, W.2), at 7.15 p.m.—Mr. N. J. Radinger: "Rust, Acid and Heat Resisting Steels" (in German).

Tuesday, February 29

INSTITUTION OF BRITISH AGRICULTURAL ENGINEERS (at the Royal Society of Arts, John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. Clyde Higgs: "Mechanisation of the Mixed Farm".

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY (joint meeting with the PHYSICAL SOCIETY OF MANCHESTER and the GEOGRAPHICAL ASSOCIATION) (at the University, Manchester), at 5 p.m.—Dr. E. C. Bullard: "Geological Time".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Dr. J. Ramsbottom: "Fungi and Modern Affairs", 3. "Fungi in Harness".*

INSTITUTION OF CIVIL ENGINEERS (STRUCTURAL AND BUILDING ENGINEERING DIVISION) (at Great George Street, Westminster, London, S.W.1), at 5.30 p.m.—Miss Letitia Chitty: "Modern Experimental Methods in connexion with the Design of Statically Indeterminate Structures".

SHEFFIELD METALLURGICAL ASSOCIATION (at 198 West Street, Sheffield), at 6.30 p.m.—Mr. J. C. Gregory: "The Technique of Metallographic Examination".

Wednesday, March 1

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—The Rt. Hon. the Earl De La Warr: "Flax Production in War, and its Prospects in Peace".

INSTITUTION OF ELECTRICAL ENGINEERS (WIRELESS SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. A. J. Maddock: "Some Applications of Thiratrons in Radio Engineering".

INSTITUTE OF WELDING (at the Institution of Civil Engineers, Great George Street, Westminster, London, S.W.1), at 5.30 p.m.—Mr. W. K. B. Marshall: "Recent Developments in the Welding of Light Metals".

Thursday, March 2

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Sir Jack Drummond: "Food Fads and Food Fallacies".*

INSTITUTE OF PHYSICS (ELECTRONICS GROUP) (in the Reid-Knox Hall, British Institute of Radiology, 32 Welbeck Street, London, W.1), at 5.30 p.m.—Dr. F. C. Toy: "Electron Microscope".

INSTITUTION OF ELECTRICAL ENGINEERS (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Dr. A. E. W. Austen and Miss W. Hackett: "Internal Discharges in Dielectrics, their Observation and Analysis".

CHEMICAL SOCIETY (LEEDS AREA LOCAL SECTION) (joint meeting with the LEEDS UNIVERSITY CHEMICAL SOCIETY) (in the Chemistry Lecture Theatre, The University, Leeds), at 5.30 p.m.—Discussion on "The Mechanism of Oxidation-Reduction Reactions" (to be opened by Prof. H. S. Raper, F.R.S., Prof. M. G. Evans and Dr. W. A. Waters).

Friday, March 3

PHYSICAL SOCIETY (in the Physics Department of the Imperial College, Imperial Institute Road, London, S.W.7), at 4.30 p.m.—Mr. A. J. Philpot: "Physics and the Scientific Instrument Industry".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5 p.m.—The Rt. Hon. Lord Rayleigh, F.R.S.: "Pebbles of Regular Shape, and their Reproduction in Experiment".*

CHEMICAL ENGINEERING GROUP (joint meeting with the GLASGOW SECTION OF THE SOCIETY OF CHEMICAL INDUSTRY and the INSTITUTION OF CHEMICAL ENGINEERS) (at the Royal Technical College, Glasgow), at 7.30 p.m.—Mr. Frank Broadbent: "Centrifuges".

Saturday, March 4

BRITISH ASSOCIATION OF CHEMISTS (LONDON SECTION) (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Dr. T. J. Drakeley: "Training for the Chemical Industries".

GEOLOGISTS' ASSOCIATION (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Prof. H. H. Read, F.R.S.: "Meditations on Granite", Part 2 (Presidential Address).

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

GRADUATES (3, temporary) for MATHEMATICS and SCIENCE at the Hammersmith School of Building and Arts and Crafts, Lime Grove, London, W.12, and a GRADUATE (temporary) for MATHEMATICS and ENGLISH SCIENCE (CHEMISTRY, PHYSICS, MECHANICS) at the Clapham College Annexe, Nightingale Lane, London, S.W.4—The Education Officer (T.1), County Hall, Westminster Bridge, London, S.E.1 (March 1).

ASSISTANT MASTER IN MATHEMATICS AND SCIENCE in the Junior Technical School—The Principal, Royal Technical College, Salford 5, Lancs. (March 1).

DIRECTOR OF THE IMPERIAL AGRICULTURAL RESEARCH INSTITUTE, Government of India—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. O.N.F. 2080A) (March 1).

RESIDENT ENGINEER (location, Northern Ireland), to take charge of Construction Work in connection with an important Power Station extension and High Voltage Transmission Lines, Switching Stations, etc.—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. D.759.XA) (March 4).

ASSISTANT IN THE HORTICULTURAL DEPARTMENT, with practical experience in Fruit Growing and Commercial Horticulture, to organize spraying operations and supervise the proper cultivation of orcharding—The Chief Executive Officer, Hereford War Agricultural Executive Committee, 4 St. John Street, Hereford (March 5).

ASSISTANT LECTURER IN THE MINING DEPARTMENT of the North Staffordshire Technical College—The Clerk to the Governors, Town Hall, Hanley, Stoke-on-Trent (March 6).

EXECUTIVE ENGINEERS, Grade IV, for the Nigerian Government Public Works Department—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. E.773A) (March 6).

IRRIGATION ENGINEER by the Government of Northern Rhodesia—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. E.784A) (March 8).

PHYSICIST—The Registrar, University College, Hull (March 9).

SENIOR DIETICIAN (woman, temporary) by the Department of Health for Scotland—The Ministry of Labour and National Service, Appointments Office, 5 Rothesay Terrace, Edinburgh 3 (March 11).

PRINCIPAL—The Clerk to the Governors, Harper Adams Agricultural College, Newport, Shropshire (March 18).

PROFESSOR OF MECHANICAL ENGINEERING in the Benares Hindu University Engineering College—The Secretary, Institution of Mechanical Engineers, Storey's Gate, St. James's Park, London, S.W.1 (March 18).

COMMISSIONS IN H.M. FORCES (a limited number) will be granted to candidates who are University-trained Biologists, preferably men with some experience of malaria or entomology—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. ONF.2057A) (March 18).

UNIVERSITY CHAIR OF ANATOMY tenable at St Mary's Hospital Medical School—The Academic Registrar, University of London, c/o Richmond College, Richmond, Surrey (March 20).

WAYNFLETE PROFESSORSHIP OF METAPHYSICAL PHILOSOPHY—The Registrar, University Registry, Oxford (April 13).

PROFESSORSHIP OF ENGINEERING SCIENCE—The Registrar, University Registry, Oxford (April 30).

DIRECTOR OF THE INSTITUTE OF MEDICAL AND VETERINARY SCIENCE, Adelaide—The Agent-General and Trade Commissioner for South Australia, South Australia House, Marble Arch, London, W.1 (May 31).

TEACHER (part-time) OF ANIMAL PHYSIOLOGY in the Department of Biology—The Principal, Chelsea Polytechnic, Manresa Road, London, S.W.3.

ASSISTANT LECTURER (temporary) in AGRICULTURAL CHEMISTRY—The Registrar, The University, Reading.

TRAINING FOR CITIZENSHIP

With so much now being said and written about the future of education, goes the very serious query : Education for whom and for what ? Incorporated in any reply to this should surely be the conception of good citizenship ; and to-day, surveying the state of his country and the world, the enlightened citizen everywhere insists that much more shall be done in this direction. It was with this knowledge of the convictions of many thinking people that the Secretary of State for Scotland early in 1943 instructed the Advisory Council on Education in Scotland "to consider how the educational system of Scotland can most effectively contribute to training in the duties, rights and practice of citizenship, and make recommendations". The considerations and findings form the basis of a report* ; it has been written clearly and precisely, and will commend itself to men of science not only for its valuable subject-matter but also as an example of the way in which such reports should be written.

Before embarking upon its investigation, the Council considered the purpose of citizenship and concluded that its objects are fourfold. It should train young people : (1) to become good husbands and wives and fathers and mothers ; (2) to develop the spirit of responsibility and of tolerant co-operation with their fellows, in work or leisure activities ; (3) to take an intelligent and independent part in the affairs of the community, both local and national ; (4) to have a sense of membership of the world community.

The Council then states quite plainly that, under prevailing conditions, the practical application of citizenship training in many schools is hindered by home and social conditions over which the schools have no control. Until slums are abolished and housing conditions greatly improved, the schools cannot be blamed if the training for citizenship which they give does not produce the desired results. But no school must be allowed to relax its efforts because home conditions make training comparatively useless or ineffective. These conditions must rather be regarded as a challenge, and the vision of better conditions in the post-war world as an incentive to increased effort.

Two main recommendations are made by the Council which, in its view, should serve as the basis for immediate action. First of all, it is strongly recommended that "the next five years be set apart as a period of experiment and of deliberate striving towards a theory and practice in training for citizenship". Secondly, it is suggested that soon after the end of the second year of the quinquennium of experiment, the Scottish Education Department should publish a report indicating the plans and experiences of the schools, whether successful or not. During the remaining period of the experiment, further reports should be published annually, and should outline the more active and successful features of the school programmes, as well as experiments

* Training for Citizenship. A Report of the Advisory Council on Education in Scotland. H.M. Stationery Office. 6*d*. net.

which have not produced the hoped-for results, thus enabling schools to make such changes in their own schemes as the experience of other schools may indicate. At the end of the term of experiment, it might be possible to decide whether local autonomy and experiment might continue to serve as a national plan of training for citizenship, or whether the plan of training should be basically similar throughout Scotland.

These recommendations cannot fail to meet with approval, not least from men and women who use the experimental method as their basis for decision and judgment. Instead of the haphazard and slipshod methods which have been the companions of educational reform, it is suggested that this controlled period of five years be used as a time of inquiry, observation and collation.

It is rightly recognized that the new importance which must be attached to training for citizenship "will involve some change of emphasis in the work of the schools. While they will continue to impart knowledge and to prepare children for life and work, they will, more than ever before, become the training ground where the future citizens will learn what they are expected to become as members of a free and democratic community; and from this point of view, what they are and what they become is more important than what they know. In our view it is not possible to adapt the present machinery of education effectively to these changed conditions without prior experiment."

The Council then discusses some of the methods by which the five-year experiment should be governed. Almost all the witnesses who were consulted consider it essential that a school should be regarded as a small community within the larger community. This is set out as the first proposal. Children should know and share in the duties and responsibilities of citizenship, and, as the child grows older, the more definite should training for citizenship become. In many schools a great tradition and a distinctive atmosphere have been built up, mainly by the personality and united efforts of successive headmasters and their staffs. The character of the future citizen and his philosophy of life will at many points be built upon the tone of his school and upon the influence and character of his teachers. This responsibility must be accepted in a very real way by the heads of the schools and must be willingly discharged by them and their colleagues. It is important, therefore, that authorities charged with making appointments to schools should secure men and women of the right personality and temperament. In order to ensure harmonious working of a school staff, governing bodies should take the heads of schools into closest consultation and endeavour to make new appointments of staff acceptable to them. Training colleges will need to exercise a more discriminating selection of intending students and should take steps to reject unsuitable students at any period of their training. Much misery would be prevented by these rejections.

The problem of backward children calls for more study, with the view of developing means of dealing with them other than by segregation. When segregation is found to be the only practicable method, this should be applied at an earlier stage than is at present customary. In the primary school, classes should be reduced to a maximum of thirty; but even under present conditions experiments should be made in handling the individual class as a small community within the larger community of the school.

In the junior and secondary schools, the present system of using specialist teachers for different subjects often means that these teachers do not see their pupils often enough to gain an intimate knowledge of them as individuals. It is suggested that the experiment be tried of appointing class masters or mistresses who would give the pupils sympathetic guidance both in and out of school. The more these teachers learn of the home conditions of their scholars the more effective would their influence be.

The appointment of prefects or monitors in senior secondary schools and the organization of a house or nation system have afforded opportunities for an excellent training in the responsibility of leadership. Experiments should now be made to cover such questions as the best methods of electing or appointing the prefects or monitors or other group-leaders. Classes might be divided for certain class-room or recreational activities into balanced groups, each with a leader and sub-leader. In all secondary schools and large primary schools which are co-educational there should be a woman superintendent; in all large schools the headmaster should be given adequate clerical assistance.

Although the boarding school is a comparative rarity in Scotland, its value as a training ground for citizenship is fully recognized by the Council. It is suggested that experiments should be made in sending secondary school pupils to such schools.

In order that school leavers may be more suitably placed in jobs, the Council recommends that the Scottish Education Department should consult with the Ministry of Labour as to what revision of the present system is needed to make it most effective. The appointment of careers masters and mistresses might be one of the means by which experiments could be conducted.

New school buildings should be functionally suitable for their purpose. They should be well equipped for the business of teaching and for those needs that may develop out of youth service and community movements of the future; where old buildings are to be retained they should be periodically revitalized.

The Council's second proposal for the five-year experiment is that there should be close and continuous collaboration between parent and teacher. A concerted plan must be evolved in which the schools, the homes, and all the other agencies concerned with children play their part. Although the parent-teacher association has not met with great success in Scotland, it is suggested that the movement be fostered and that other movements for collaboration be inaugurated.

The third proposal is concerned with moral and religious training. Experiments should be made in giving definite lessons in the principles of right and wrong conduct. The teaching of 'human relations', in the course of which every child considers the results of his own and other people's actions, good or bad, should be tried. This is already in vogue in the State of California and has given valuable results. An experimental schools code of good conduct, similar to scout law, could be produced and the effects of the code in schools carefully observed.

In the respective spheres of responsibility of the Secretary of State and of the Education Authorities for religious instruction, the Council considers that no change is desirable. The true Christian spirit should pervade the whole school and nothing should be done which might create the impression of hypocrisy. The practice of holding a morning service should be encouraged and on special occasions services in nearby churches should be encouraged. Definite periods should be set aside for religious instruction and should include periods other than those at the beginning or end of a meeting of the school. Close co-operation between the churches and the education authorities in each area should be constantly practised.

Special study and experiment is needed on the training of teachers for religious subjects. But the Council is unanimous in recommending that only believing Christians should be entrusted with the duty of giving instruction on religious subjects in schools. The qualifications of the teachers concerned will vary with the type and age of pupil; the Council proposes to issue a further report relating to this point.

Proposals for moral and religious training lead naturally to the fourth proposal, which deals with æsthetic training. Here it is emphasized that the appeal of beauty plays an important part in the building up of the good citizen. No education is considered complete unless an attempt is made to develop in the child some æsthetic appreciation of art, music and the beauties of Nature. Further experiments should therefore be made into the methods of teaching children how to appreciate line, form, colour, tone and rhythm, while every child should be given the opportunity of drawing and painting and practising the crafts for which he or she shows aptitude. Direct participation in musical activities should be encouraged, and the appreciation of good music should be taught at every opportunity. The facilities offered by the Council for the Encouragement of Music and the Arts and the British Institute of Adult Education in their presentation of good music, drama and art exhibits should be freely used. One must commend the Council for a proposal which, if generously interpreted and acted upon, might ultimately offer to many people the solution of their leisure problems.

Men of science will readily accept the next proposal, which deals with the promotion of good health. For the integration of the personality, bodily health is of prime importance. From their earliest years children should be taught the elementary facts of personal hygiene; physical training should form part of the daily routine of all schools and, so far as possible, should be carried out in the open air. Parents, too, should be reminded of the need for adequate sleep for their children.

Another proposal deals with the prevention of accidents. It cannot be too strongly stressed that the rules of safety are not inherent and must be taught. There is scope for further experiment and for co-operation between school, home and other agencies.

The Council regards it of first importance that all children should be instructed in the simple facts of sex, and suggests the appointment of a committee to investigate methods by which sex education might be introduced into schools. This committee, no doubt, will use much of the material and derive inspiration from the recent publication of the Board of Education on this important subject (NATURE, **152**, 582; 1943).

The eighth proposal towards the training of the good citizen is concerned with the contribution of the individual school subject. It is suggested that English, geography, history and civics each has a special contribution to make towards training for citizenship. No one would wish to deny the peculiar importance of the subjects mentioned; but the omission of any reference to the value of science as a social discipline must be strongly deprecated. The Council should seek further evidence and rectify this unfortunate omission immediately.

A knowledge of local history and tradition as preparation for citizenship is of special significance. Schools should be invited to concern themselves with local interests and the revival of historic ceremonies and festivals. This would encourage the growth of the community spirit and would do much to awaken in young people the desire to take part in the development of their own neighbourhood. Later the need for positive teaching would arise, and the child should be made aware, through facts within his personal observation, of the responsibility which local authority and the central government services are discharging for the health, convenience and security of the community. Many experiments could be undertaken to investigate the most suitable methods of teaching these positive aspects of civics.

The last proposal in training for citizenship relates to the contribution of the several parts of the educational system. Each type of educational organization, from nursery school to university, has its own peculiar part to play in the making of good citizens. The Council recommends, therefore, that comprehensive investigations be set in process to consider the special place of each type of educational organization in serving the needs of the future citizen; special attention should be given to mentally backward children.

The report concludes with a valuable statement about the real origins of juvenile delinquency and their amelioration. It is scarcely necessary to say

that there is no sovereign remedy which is likely to have an immediate and substantial effect on the problem of the young offender; but the Council rightly emphasizes that many of the suggestions which it has made cannot fail to take effect in the long term. The major cause of juvenile delinquency often lies in the home. With the coming of the educational facilities outlined in the Education Bill and the provision of better homes and healthier conditions of living, the evil of juvenile delinquency should be considerably reduced. Where delinquency is obviously not due to home conditions, the schools must do everything possible to alleviate the handicaps or maladjustments at the root of individual cases of delinquency. The problem of truancy should be attacked in its early stages; school attendance officers might profitably be replaced by school welfare officers. Children whose delinquency is due to inherent mental defect should be referred to child guidance clinics, the total number of which should be considerably increased.

Lack of opportunity for healthy exercise is a frequent cause of juvenile delinquency, and an extension of holiday facilities in the country for city children should be urgently considered, as should the provision of an increased number of playing fields.

Much of the material in this report is applicable to the educational organization in any country, and the people of England and Wales would do well to appropriate for themselves most of its spirit and many of its recommendations. A great deal is expected from the Advisory Councils for England and Wales, the constitution of which is adumbrated in the Education Bill. These Councils should copy their Scottish counterpart and direct their early attention to ways in which good citizenship can be developed. In their deliberations they should take pains to point out that, however paradoxical, good citizenship is not confined within national boundaries.

Recently there has appeared a number of White Papers on various aspects of education. Most of them have been concerned with pressing problems of current importance and have presented the problems with dignity and earnestness. Now, if one reads the signs of the times aright, the time has come when we have to decide one way or the other about issues like the one outlined in this report; and having made our decision, we must then translate it into action. Future developments must be planned so that the most needed requirements are given priority for action. Here we must be on our guard that the more intangible requirements like good citizenship shall not be shelved in favour of the more material and obvious aspects of reconstruction. If we decide now to institute adequate schemes of citizenship training along the lines indicated in this report and, equally important, inculcate a positive attitude towards world citizenship as set out in Brimble and May's recent book*, many of the other things will follow. The good citizen will see to that.

AN ARISTOTELIAN ON LOGIC AND GEOMETRY

(1) Études sur la connaissance mathématique
Par Prof. Thomas Greenwood. Pp. viii+112. (Ottawa: University of Ottawa, 1942.) 1 dollar.

(2) Essais sur la pensée géométrique
Par Prof. Thomas Greenwood. Pp. 100. (Ottawa: University of Ottawa, 1943.) 1 dollar.

(3) Prolégomènes à la théorie des quanta
Par Prof. Thomas Greenwood. Pp. 61. (Ottawa: University of Ottawa, 1943.) 60 cents.

THERE is now a great deal of coming and going between natural science and metaphysics. On the mathematical-physical side there is a succession of writers from Whitehead and Russell to Jeans, Eddington and Dingle, while professional philosophers such as the late Prof. Susan Stebbing have studied the new atomic and cosmic physics in order to find whether they have any metaphysical repercussions. The volumes under review, which are published by the French-Canadian University of Ottawa, witness to the interest that is now taken in these problems all over the world.

A worker of real eminence in one of the two fields is apt, when he crosses over into the other, to make mistakes. In view of the difficulty and importance of what he is trying to do, there will be general agreement that the proper attitude to take on these occasions is a charitable indulgence; and of this, it must be said, Prof. Greenwood is often in need so far as concerns one of these three books, namely, that on quantum theory; as the following quotations will show:

"Un corps noir à une température donnée émet une série de lignes coloriées qu'on nomme son spectre" (p. 10).

"La différence de fréquence de deux raies quelconques d'un spectre est la fréquence d'une autre raie du même spectre" (p. 10).

"Un corps noir . . . à 500° C. commence à donner des rayons monochromatiques; à 1200° C. le rayonnement est blanc; à 3,400° C. il atteint son intensité maximum" (p. 11).

"D'après le principe de la moindre action de Maupertius, l'action d'un électron vibrant avec une énergie E serait $\int mvds = E/\nu$" (p. 13).

"Les rayons-γ ne sont que des courants rapides d'électrons" (p. 15).

"Pour toute équation differentielle, on peut trouver des solutions finies, universelles et continués seulement si le paramètre contenu dans l'équation a des valeurs définies" (p. 25).

"Une matrice est *symétrique*, lorsque tous ses éléments situés symétriquement par rapport à la diagonale principale ont leurs suffixes égaux, mais intervertis" (p. 33).

It is to be regretted that the author did not submit his manuscript to some competent physicist before sending it to the printer.

This unfortunate venture should not be allowed to prejudice the reception of the other two works, which contain much valuable and stimulating reading. The first of the "Études" is devoted to mathematical logic, where Prof. Greenwood is on his own territory and has many interesting things to say. He belongs to the conservative wing, and deplores the tendency of some writers to regard the Aristotelian-scholastic

logic as obsolete. To many it might seem as if the superiority of the new symbolism was now beyond all question: for it has triumphantly solved problems with which the traditional logic trifled impotently for two thousand years. There is, however, another side to the question; it is necessary to distinguish between two different aims which the logician may propose to himself: he may wish to increase his power and facility in drawing inferences, or he may wish simply to investigate the theory of logic in itself. For the former purpose the advantages of the symbolism are indisputable; but in regard to the latter, the Aristotelians do not admit inferiority. Perhaps their most vulnerable spot is the doctrine of relations; more than eighty years ago they were teased about it by De Morgan, who issued challenges such as "To prove by traditional logic that *if cows are animals, the tails of cows are tails of animals*", and "To deduce the classes of men specified in *the non-ancestors of all non-descendants of Z*". Prof. Greenwood proposes to gather relations into the Aristotelian fold by considering the relation and the related predicate as *the* predicate, and the judgment as a declaration or denial of identity between this and the related subject, so that all relations are reduced formally to those expressed by *is* and *is not*; working out this idea, he claims that the calculus of relations can be added "comme un nouveau chapitre à la logique classique, sans devoir le présenter comme une innovation exigeant une transformation complète des bases de cette logique".

The "Études" include interesting and learned discussions of the mathematical ideas of Aristotle and St. Thomas, and the "Essais" contain an entirely original treatment of the foundations of Euclidean geometry.

In conclusion, one may refer to an opinion of Prof. Greenwood's (in support of which he quotes St. Thomas), that "Le caractère purement formal des sciences mathématiques rend celles-ci bien plus faciles à étudier que les autres sciences: et par conséquent elles sont particulièrement avantageuses pour l'éducation des jeunes". It is interesting to speculate how St. Thomas would have handled the modern agitation to allow girls to learn botany instead of mathematics, because mathematics is too hard for them.

E. T. WHITTAKER.

RESEARCH IN SOCIAL ORGANIZATION

The Peckham Experiment

A Study in the Living Structure of Society. By Dr. Innes H. Pearse and Lucy H. Crocker. (Published for the Sir Halley Stewart Trust.) Pp. 334+16 plates. (London: George Allen and Unwin, Ltd., 1943.) 12*s*. 6*d*. net.

THERE was a time I wished I lived in Peckham, for in 1926 the Pioneer Health Centre was opened there by a group of young people who set out to study health and to foster conditions in which it could be maintained. They offered to families the facilities of a well-provided social club, and a periodic health overhaul. It would have been nice to be one of their 'guinea pigs'; the social experiment alone was commendable, and the possibilities of a new kind of medical research seemed enormous. The first two books published by the Peckham 'biologists', "The Case for Action" (1931) and "Biologists in Search of Material" (1938), were disappointing, but it was perhaps too early to decide whether they were a little 'cranky', or merely picturesque. To social biologists, however, "The Peckham Experiment" is even more disappointing. It gives a lengthy exposition of the experimenters' philosophy and descriptions of life at the Centre, but it reports very little advance on the results of research published in its predecessors. These results were certainly interesting and sometimes unexpected. For example, only about 10 per cent of the Centre members had no physiological defects, and about 68 per cent had some disorder but were seemingly well. The high incidence of worm infestation, reaching so much as 41 per cent in boys of 6–10 years of age, is surprising. Two further interesting findings published earlier but not unfortunately expanded in this book are the frequent occurrence of a state of mild chronic debility and the profound physiological effects of night work.

As is to be expected, the results of periodic medical examinations give the Peckham workers plenty of support for their belief that "nothing short of periodic health overhaul on a national scale can lead to the rational application of medical science for the elimination of Sickness". Health centres have the opportunity of studying groups of the population at present far too little known to medical science: the normal group, the group oblivious of organic disease in its early stages, and the group unpleasantly aware of clinically uninteresting chronic debility. The Peckham biologists have demonstrated something of the importance of these groups, but we still await indications of an intensive research programme designed to take advantage of their material. The newness and difficulty of research on the health and sickness of a whole population possibly makes impatience unfair. But most readers of this book will wonder whether they will ever feel satisfied that the research is on the right lines. It is difficult not to feel that their preconceived ideas about "the Living Structure of Society" stand in the way of the experimenters.

The authors say "We claim to have defined the unit of Living. It is not the individual, it is *the family*. This has opened up a new field for experiment into social organization. . . ." But they deliberately rejected necessary controls for their experiments on the "unit of Living", for they refused to consider the 'non-family' by making it a condition of membership of the Centre that the family should join as a whole. Thus their observations were limited to a selected population from which isolated individuals and broken families were excluded. Moreover, the experimenters threw away a unique opportunity for studying the effects of family disintegration (as well as those of other incidentals of war such as the black-out, air-raids, changes of diet), for "The Centre's activities were suspended at the outbreak of war, September 1939, owing to the inevitable dispersion of the family unit in war conditions".

Further, the Peckham biologists' concept of the family as a functional unity or organism leads them to deduce a new physiology. Some quotations will illustrate its unusual flavour: ". . . by the time fertilisation has taken place the blood of the mother has been sensitized and attuned to that of her mate, father of the embryo. Thus, from the moment the new individual begins to develop, there is already a *physical* basis for a 'functional organisation' between the three individuals of the growing family" (p. 34). When a couple announces that conception has

occurred the physical changes which take place in the pregnant woman are described to them: "Her tissues become fluid and softened so that, for instance, in some you can almost bend the bones under the finger. All the tissues undergo this change—liver, bones, hair, eyes, brain—all are flooded with the circulatory fluids of the body so that their essence seeps out and is carried round in the blood to the womb where the growing child can draw upon it for its nourishment and growth" (p. 87). It is perhaps not surprising that one of the very few research projects the authors mention is not of great practical importance: "Experiments were under way at the Centre, before war brought our work to a close, to find bio-chemical evidence in the father of parenthood occurring in the family".

In evaluating the work of the Peckham Pioneer Health Centre, a biologist is driven to judge the social and scientific aspects of the work very differently. There can be no doubt that the members of the Centre benefited socially and medically from its services; but the scientific results published in these books do not seem commensurate with the opportunities offered. I think it is important to indicate that the defect lies not in the nature of health centres, but in the preconceived ideas of these experimenters. While great credit must be given to the Peckham biologists as pioneers in the health centre movement, it would be a pity if further progress in such an important technique of medical research were prejudiced by their views and methods, which many people will find scientifically unacceptable.

M. L. JOHNSON.

CHEMISTRY OF LARGE MOLECULES

The Chemistry of Large Molecules

Edited by R. E. Burk and Oliver Grummitt. (Frontiers in Chemistry, Vol. 1, published under the auspices of Western Reserve University.) Pp. xii+313. (New York: Interscience Publishers, Inc.; London: Imperia Book Co., Ltd., 1943.) 3.50 dollars.

"THE Chemistry of Large Molecules" is the first volume of a new series entitled "Frontiers in Chemistry" and is composed of eight sections written by experts in the field of macromolecules. The first two sections, compiled by Dr. H. Mark, give a rather brief account of the kinetics of poly-reactions and of the mechanism of condensation, and a concise record of the information available from X-ray study of large molecules. Dr. Kraemer then discusses in the next section the colloidal behaviour of solutions of macromolecules with special reference to the relatonship between viscosity and molecular weight. The same author also contributes a good summary of the application of the ultracentrifuge to the study of large molecules.

Section 5, compiled by a team of three experts, is an advanced mathematical treatment of the elastic-viscous properties of long-chain molecules, while the electrical properties are discussed by Dr. Friess in Section 6. The work of Marvel and his collaborators on vinyl polymers is well known, and is here summarized in Section 7 by Dr. Mark himself. The last section in the book deals with the chemistry of cellulose and cellulose derivatives, and is written by Dr. Ott. Each section is supported by an adequate bibliography.

In a foreword the editors of this book explain that Western Reserve University conceived the idea of inviting scientific workers distinguished in particular fields of chemistry to give two lectures each on his particular subject, and the book is based on such lectures. As the title of this series of books suggests, the subject-matter is to be found on the "Frontiers of Chemistry". It is therefore definitely a book for the expert, and of particular value to those who are investigating the course of polymerization and the theory of the reactions.

Much publicity is given at present to macromolecular structures; but the reader will find in this book practically nothing of the spectacular industrial applications of these materials. Instead he will find fundamental mathematical and physico-chemical reasoning, and it would be true to say that without a good knowledge of these sciences the reader will find the book heavy reading.

D. D. PRATT.

SKOKHOLM

Dream Island Days

A Record of the Simple Life. By R. M. Lockley. Pp. 144+8 plates. (London: H. F. and G. Witherby, Ltd., 1943.) 10*s.* 6*d.* net.

FOR "some to discover islands" is a recognized career for men, like "some to the wars", or "some to the studious universities". Such islands are mostly far away; but to rediscover the forgotten and reoccupy the abandoned ones is work for R. M. Lockley, Compton Mackenzie, Fraser Darling, Seton Gordon, and other men of like calibre. For a man's island is his kingdom, and becomes his paradise; and a bird-lover among his own island-birds lives, as it were, in Eden.

This book is not a new one. It mostly repeats what Mr. Lockley wrote about his "Dream Island" some fifteen years ago; but he lived there for years after, until there was no more peace anywhere, and now he tells the 'simple story' of his island-life, with wife and child, among the wildfowl. The usual lover of birds has his life embittered by the sportsman and his game-keeper or 'vermin-killer', who spend their selfish lives slaughtering falcon and buzzard, crow and raven, merlin, jay and magpie, and many another beautiful creature which has its place in poetry and its corner in the kindly hearts of men. But on one's own island one lives at peace with all bird-kind, even—by a stretch of charity—with the great black-backed gull.

Mr. Lockley's book on "Shearwaters" was one of the great bird-books of our time. Now we may read again of that strange sea-fowl, which meets us in Homer and in Virgil and in Ovid; which is here by thousands; which flies from Pembroke to the Bay of Biscay for its dinner; which sits for two full months on its solitary, subterranean egg; which feeds its downy chicken for two months more, and then leaves it lonely and desolate (but a delicious morsel) until hunger drives it to seek the unknown sea. We walk round the little island; pass by 'Puffin-town' with its population of 40,000 puffin-souls; tread on wild-thyme, campion and sea-pink; watch the pair of ravens and the pair of peregrines, part-owners of the place; and see the few choughs and many carrion crows, the whin-chats and the meadow-pipits, perhaps the host of migrants in the spring; and the grey seals on the beach below the cliff. A wonderful place, and a delightful book—too good for anybody but a naturalist.

D'ARCY W. THOMPSON.

Mathematical Recreations

By Prof. Maurice Kraitchik. Pp. 328. (London: George Allen and Unwin, Ltd., 1943.) 12s. 6d. net.

THERE is reason to suppose that in at least some cases an interest in mathematics develops out of an interest in puzzles and problems, rather than from an interest in straightforward arithmetic. For those whose interests in mathematics have already been aroused, there are collections of mathematical recreations, of which the best known to the British reader are W. W. R. Ball's "Mathematical Recreations and Essays" and H. E. Dudeney's "Amusements in Mathematics". Ball's book, especially as revised by H. S. M. Coxeter, lays the emphasis on the mathematics. However apparently frivolous the starting point, the reader soon finds himself guided, gently but firmly, into an approach towards important mathematical principles. Dudeney's book, on the other hand, lays the emphasis on the amusements, and appeals more to the type of person who delights in listening to the "Brains Trust".

Prof. Kraitchik's book, based on a course of lectures delivered in New York, may be regarded as a revised edition of his "La Mathématique des Jeux" (Brussels, 1930), enriched by his nine years editorship of the periodical *Sphinx*. His treatment is something like Ball's, but not quite so serious, and with much more attention to problems connected with games, including not only chess, "checkers" (draughts), "craps" (dice) and dominoes, but also several games very little known in England. The discussion of the chess rook's moves leads to an introduction to the theory of groups. There are twelve chapters: mathematics without numbers, ancient and curious problems, numerical pastimes, arithmetico-geometrical questions, the calendar, probabilities, magic squares, geometric recreations, permutational problems, the problem of the (chess) queens, the problem of the (chess) knight, and games. The longest two chapters are on numerical pastimes, which contains a good deal about the theory of numbers, and magic squares. The chapter on geometric recreations contains several interesting diagrams of mosaics. H. T. H. P.

A German Physics Reader

By J. E. Calthrop. Pp. 83. (London and Toronto: William Heinemann, Ltd., 1943.) 7s. 6d. net.

THE steady growth of physics places a great strain upon students and teachers of the subject and a continual look-out is kept for means of lightening the work by omissions. Unfortunately, the study of German cannot be omitted. If no more physics were published in German, it would still be necessary for many years that the physicist should at least 'muddle through' a passage in German well enough to use the German handbooks and to read research papers in his subject. There are three minimum requirements. An elementary knowledge of the grammatical and constructional difficulties of scientific German, a basic vocabulary and a thorough knowledge of physics to make up for deficiencies in the first two.

The present volume can supply the second requirement—an excellent basic vocabulary. As the title implies, the book consists chiefly of passages in German on physics, and no help at all is given with grammar. Section 1 contains eleven extracts on the history of physics, ranging in subject from Brownian movement to radioactivity. A translation of each passage is given on the opposite page. Section 2 gives thirty passages, each with its own vocabulary. Section 3 reproduces more than thirty science German questions from University of London examination papers. There is no collected vocabulary or index at the end of the book and the beginner would need also such a volume as Wiener's "German for the Scientist" (Bell, 1943). The price seems rather high by comparison with Wiener's book, but there is no doubt that the selection of passages is the most comprehensive so far published for the physicist. Each extract is of interest for its content and is full of words commonly occurring in the literature. The book can be strongly recommended. W. H. G.

An Introduction to Pure Solid Geometry

By Dr. G. S. Mahajani. Second edition. Pp. xiv+104. (Poona: Aryabhushan Press, 1943.) 3 rupees.

THIS is the second edition of a book originally published in 1940. It is designed for intermediate and inter-science students at Indian universities. Its five chapters deal with lines and planes in space, the tetrahedron and parallelopiped, mensuration of prisms and cylinders, the sphere, solid angles and polyhedra. An appendix is provided in which the volume of a prismatoid is discussed. An excellent set of miscellaneous exercises then follows.

In order to clarify the subject and thus avoid any confusion in the mind of the student, the author has attempted to cover the essential subject-matter in the smallest number of theorems—and the attempt has been very commendably carried out. Many exercises are given which can be regarded as bookwork, and to several of these, solutions are indicated. As with the author's "Elementary Analysis", the exposition is particularly lucid and should give the student a thoroughly clear perception of the fundamental principles of solid geometry. In this new edition, the text has been rewritten and rearranged. Several new paragraphs have also been added in order to render the relevant treatment self-contained. The number of exercises, too, has been increased. The book is a model of mathematical precision and clarity, and should be very useful as well as stimulating to all students of the subject.

Air-Borne Infection

Some Observations on its Decline. By Prof. Dwight O'Hara. Pp. x+114. (New York: Commonwealth Fund; London: Oxford University Press, 1943.) 8s. 6d. net.

CHANGE in virulence of certain diseases with the passage of years is a well-recognized phenomenon. Nowhere is this change so marked or, relatively, so rapid as in the diseases of the respiratory system. The last twenty-five years have seen a tremendous reduction in the mortality-rate from respiratory infections, and Prof. O'Hara has surveyed the possible explanations for this decline. He ascribes the decline to increased biological resistance rather than to any public health or therapeutic measures. Many will agree with the author in his contention that active immunity is better than passive, and that an otherwise healthy child should acquire its full immunity through having a disease such as measles rather than by being partially protected by convalescent serum. The observations on the common cold as an entity and as an abortive form of other respiratory diseases are of particular interest. The book as a whole is worthy of attention from specialist and general practitioner alike.

Lessons in Elementary Analysis

By Dr. G. S. Mahajani. Third edition. Pp. xiii+298. (Poona: Aryabhushan Press, 1942.) 6.4 rupees.

THIS useful book, first published in 1929, was reviewed in NATURE of November 7, 1936. Being designed to cover the analysis required for the bachelor's degree at most of the Indian universities, it has evidently well served its purpose, for a second edition was issued in 1934, and this third edition in 1942. There are twelve chapters devoted to the arithmetic continuum, the theory of limits, infinitesimals, continuity, mean value theorems, Taylor's theorem, integrals, including a treatment of mean value theorems and infinite integrals, uniform convergence, inversion of operations and Fourier series. While the general plan of the course remains unchanged, advantage has been taken in this edition to make several important additions. Thus, Landau's method of proving the second mean value theorem now appears, while a note on Frullani's integral is given in the addendum. Chapters 9 and 10, on infinite integrals and uniform convergence, have been rewritten, and the number of illustrative exercises at the end of each chapter has been increased.

The exposition is exceptionally clear and quite rigorous. While the lessons have been skilfully woven into a thoroughly coherent course, each chapter is almost a separate entity and can be studied as such. The sets of exercises also should serve to stimulate the student to further study.

Pasteurisation

By Harry Hill. Pp. viii+152. (London: H. K. Lewis and Co., Ltd., 1943.) 10s. net.

DESPITE its comprehensive title, this is not a treatise on pasteurization generally, but deals only with a relatively few, though important, aspects of the pasteurization of cow's milk. Nevertheless, the author goes outside his title to include sections on sterilization of milk, on homogenization and on ultra-violet irradiation of milk.

The value of this book lies, not in the first 34 pages, in which a case is made for compulsory pasteurization, but in two subsequent chapters, one on design of plant used for heat treatment of milk and the other on methods of control of the efficiency of such plant. Everyone dealing with the designing, erecting, licensing and management of plants for the commercial heat treatment of milk could read these pages with advantage. The book's appearance is particularly opportune for those who, if the recent White Paper "Measures to Improve the Quality of the Nation's Milk Supply" (Cmd. 6454) becomes law, will have additional duties to perform either of an advisory or control character in respect of heat treatment of milk.

Printing, paper and binding are all good; but it is to be hoped that the complete absence of diagrams will be remedied in the next edition.

Clubs and Club Making

By various Authors. Issued by the National Association of Girls' Clubs. Edited by Dr. J. Macalister Brew. Pp. 104. (Bickley: University of London Press, Ltd., 1943.) 2s. net.

THE launching of the Service of Youth movement soon after the outbreak of war has been followed by a growing interest in the means whereby adolescence could be most ably guided towards balanced maturity. There is an increasing number of people who are seeking to serve in this important and valuable work and the number will continue to grow with the birth of the new Education Bill. To help these potential youth workers the National Association of Girls' Clubs has produced this little book. It has been compiled from a series of pamphlets which have been previously issued by this and the corresponding boys' organization, the National Association of Boys' Clubs. The description of various club activities, as well as club administration, is presented with sympathetic understanding of beginners' problems, while the meticulous attention to detail on practical issues leaves little to be added. One readily agrees with the authors' conclusion that the book makes no claim to literary excellence, but that should in no way detract from its usefulness as a handbook for prospective and practising club leaders.

Aerodynamics of the Aeroplane

By W. L. Cowley. (Nelson's Aeroscience Manuals.) Pp. 201. (Edinburgh and London: Thomas Nelson and Sons, Ltd., 1943.) 5s. net.

ADMITTEDLY it is difficult to write an elementary book on a mathematical subject like aeronautics, to give the main principles and yet steer clear of the more difficult mathematics involved. The attempt to do this has been made in this book, and to give an elementary survey of present-day aerodynamic conceptions to students of matriculation standard.

The young student will find a great deal to 'bite' at, but on the whole he is likely to find it rather 'heavy going' to digest it. The presentation of the material might have been done in a more interesting and more inspiring manner. The beginner is made to realize that the subject is difficult (as it undoubtedly is), but it probably could be made to *appear* more simple by including many more diagrams; simple diagrams mean much to a young student and are a great asset in a book of this type.

Some parts of the book are very readable and will be enjoyed by the serious student; the pages devoted to the various systems of units are a useful feature. On the other hand, certain other topics, for example, the distinction between mass and weight, could probably have been disposed of in less space.

For a small book the index is very comprehensive, and there are two chapters at the end intended mainly for more advanced students.

Borderlands of Psychiatry

By Prof. Stanley Cobb. (Harvard University Monographs in Medicine and Public Health, No. 4.) Pp. xiv+166. (Cambridge, Mass.: Harvard University Press; London: Oxford University Press, 1943.) 2.50 dollars.

THIS volume contains a series of essays on a variety of subjects, which, as the author says, are neither orthodox medicine, nor psychiatry, nor neurology. The psychiatric aspect of a number of nervous disorders is considered. These include disorders of speech, of emotion and of consciousness.

Apart from the primary concern with the importance of psychiatric treatment in these conditions, which is extremely interesting, the book is noteworthy for clear explanation of the anatomical relations, so far as they are known, of the diseases described.

FUNCTION AND FUTURE OF COLONIAL GEOLOGICAL SURVEYS

DURING the past few years, attention has been directed, from time to time, in NATURE and elsewhere*, to the importance of the work of geologists, to the widespread ignorance, in Great Britain, of geological science, and to the consequent lack of appreciation of the many services which geologists can and ought to perform for the common good. The immediate seriousness of the position lies not so much in the fact that this ignorance should prevail among the community at large, as in the realization that it extends into the administrative and governing classes, both civil and military. There is, it seems, a consensus of opinion that this is the existing state of affairs.

While it may be true that it is often recognized, if not very clearly, that there is a connexion between geology and the production of minerals, it is less commonly realized that geologists are able to render equally important, if less obvious, services in furtherance of other activities closely bound up with human welfare, such as agriculture, civil engineering and, not least, questions of water supply.

The discovery of valuable mineral deposits as a direct result of geological exploration provides from time to time a striking illustration of the importance of such a survey; but it is far from easy to demonstrate to the layman the potential value of the day-to-day work carried out by geologists, including the contributions to pure geology made by government servants. It is nevertheless true to say that the connexion between pure and applied geology is a very close one. The rare mineral of yesterday, the occurrence of which has been recorded for scientific reasons, in many cases has acquired later on an unforeseen commercial value. Similarly, the finding of some obscure fossil in the field, and its identification in the laboratory by a skilled palæontologist, may have important and perhaps immediate consequences in industry. The location of good water supplies, a service in many cases requiring the advice of a skilled geologist, is also work the value of which is not easily assessed. Of not less importance, too, is the fact that the geologist who knows his terrain thoroughly is not infrequently able to give advice that results in saving the community large sums of money that otherwise would have been wasted.

All these considerations suggest that a wise and foreseeing government would be well advised to establish and maintain properly staffed and equipped Geological Surveys, particularly in new and relatively little-known territories such as the British Colonies; and to ensure that the scientific side of the work is not unduly subordinated to the more immediate and obvious economic requirements.

Nevertheless, it still seems to be the case that, even in administrative quarters where there is some appreciation of the nature and functions of a Geological Survey, there is still incomplete realization of the purely economic value of the services such a Survey can render, and hence a lack of willingness to ensure that Geological Surveys under their control are adequately financed.

The repercussions of this state of affairs on the development of the British Colonial Empire were debated recently at a joint meeting of the Geological Society of London and the Institution of Mining and Metallurgy*, which had been specially convened to discuss the "Contribution of Geological Surveys to Colonial Development, and the Future of Colonial Geological Surveys". The debate centred round an address on this subject given by Sir Edmund Teale, formerly director of the Geological Survey of Tanganyika Territory. Prof. W. G. Fearnsides, president of the Geological Society, occupied the chair during the earlier part of the meeting, and his place was taken later by Sir Lewis Fermor, vice-president of the Institution of Mining and Metallurgy, and formerly director of the Geological Survey of India.

In his opening remarks, Prof. Fearnsides stated that the meeting had been arranged as a result of representations made to the Society by some of its fellows, resident abroad, who, being servants of the State, were dissatisfied with the conditions existing in certain Geological Surveys. In view of the economic functions of Geological Surveys, the Council had thought it desirable to seek the co-operation of the Institution of Mining and Metallurgy, as representing the metal-mining interests in Great Britain, and thereby to secure a much stronger and more professional representation at the meeting.

Sir Edmund Teale first of all pointed out that, in view of the attention now given to post-war planning, the time seemed opportune to discuss the extent to which Geological Surveys can play a part in the economic development of British Colonies. He then spoke at some length on the "complete misconception which seems to exist in high places concerning the purpose, scope, requirements and results of the work of Geological Surveys", in the following terms:

"Profound misconception exists, even among some of the highest of our Colonial officers, about the valuable work that has already been accomplished by these geological departments, and this misconception has resulted, even in the best periods, in the total inadequacy of the financial provision made for essential field work, in the reduction, in more critical times, of the existing staff, and in the failure to fill positions left vacant by the retirement of the heads of the Geological Surveys. The view is held by the officers in charge of the finances of the Colonies that Geological Surveys are not revenue-producing departments. This will appear strange to mining engineers and others familiar with the economic aspects of geological work; but there is abundant evidence of the almost complete unawareness among the chief officers of the Crown of the substantial revenue, besides other benefits, which is the direct result of discoveries of mineral deposits made by these Surveys.

"It is clear, as was shown in a short paragraph in an article in *The Times* of September 15, 1943, on tropical African Colonies, that in the view of high authorities the work of Colonial Geological Surveys finishes with mapping, and that that work is now nearly complete! Further, in certain Colonies, Geological, Mining, Survey and Lands Departments have all been merged under one Director, and he without any special training or experience in any of these subjects; many very unsatisfactory situations have thereby been created. In another Colony,

* *Abstr. Proc. Geol. Soc.*, No. 1399, 11 (Dec. 28, 1943).

mining and geological sections are combined under a non-technical director selected from the Administration Department. The mining community has never been satisfied with this arrangement nor has the geological section received the support and encouragement it merits. A great lack of uniformity of conditions prevails throughout the Colonies undertaking geological work, notwithstanding the existence of a professedly unified Colonial Geological Service.

"Water-supply investigation suffers from a wide divergence of control in the different Colonies and even a lack of consistent policy within a particular Colony. Thus at one period as many as six departments were engaged independently upon water-supply. The present policy, in general, is to use the Geological Survey to direct these activities, although in one Dependency control has recently been removed, first to the Railway Department and then to the Public Works.

"The temporary or intermittent character of some Geological Surveys, though often the result of varying financial conditions, is also partly attributable to this ignorance of the practical value of geological work. In British Guiana, Jamaica, Nyasaland, Tanganyika, and elsewhere geological work has been intermittent and the gaps have seriously retarded the systematic survey of these territories. In consequence, when certain economic demands arose, there was a lack of preparedness to meet them. Some countries, like Fiji, have never had a Geological Survey, while in others, like Kenya, there was undue delay in establishing one.

"This complete misconception of the purpose and results of geological work is also exemplified in the use of geologists for duties other than those for which they have been trained and which they are engaged to undertake: for example, the using of a geologist as an Inspector of Mines, as a District Commissioner or as an Agricultural Officer, and the overloading of him with routine clerical work or with an undue amount of topographical survey.

"A number of examples might be quoted in which the failure to obtain geological advice upon engineering problems, such as railways, bridge and dam sites, has been very costly, both financially and in the consequent interference with public services.

"A lack of continuity of policy regarding long-range systematic geological work has resulted in a lack of balance whereby an undue amount of attention has at times been given to one branch of survey work at the expense of other equally important branches."

Sir Edmund gave the accompanying statistics of the amount and value of the mineral production of the Colonial Empire.

Table 1 is of particular interest, since it shows the revenue accruing directly to the Colonial authorities through the exploitation of mineral deposits actually discovered by Colonial Geological Surveys. Sir Edmund pointed out that, while the total royalties received from the diamond industry alone in the Gold Coast, up to 1939, amount to £424,830, the annual expenditure on geological survey is only £7,000. In other words, this royalty alone would pay for the cost of the survey for sixty years. In the Colony and Protectorate of Sierra Leone the discrepancy, he stated, is even more striking. The Colony at present employs only one geologist, but the estimated value of the mineral production was more than 1½ million pounds, providing a direct revenue to the Colony of nearly £175,000.

TABLE 1.—PRODUCTION AND VALUE OF CERTAIN MINERALS RESULTING FROM THE DISCOVERIES OF COLONIAL GEOLOGICAL SURVEYS[1].

Mineral	*Production*	*Value*	*Royalty*	*Remarks*
		GOLD COAST		
Diamond	14,139,683 carats	£7,613,186	£424,830	Production represents exports to end of March 1939. Diamond export tax to end of December, 1939.
Manganese ore	5,341,308 tons	£10,062,594	—	Manganese ore is wet ore for the earlier years and dry ore for later years.
		SIERRA LEONE		
Iron ore	2,750,000 tons	£1,497,373[2]	—	Diamond profit tax 1935 to 1938.
Diamond	2,616,104 carats	£3,275,402[2]	£466,818	Quantity refers to production, value to exports. Values of production not available, but should not vary greatly from exports.
		NIGERIA		
Coal	5,546,000 tons	£1,860,000	—	To end of March, 1939. Coal mining being a Government industry, the value refers to expenses incurred in mining, no profit being added.

ESTIMATED RESERVES, NO PRODUCTION YET

GOLD COAST	Bauxite	250,000,000 tons.
NYASALAND	Bauxite	60,000,000 tons.

[1] Information supplied by the Mineral Resources Department of the Imperial Institute. Figures are cumulative from the earliest recorded production or export. Later figures are not generally available for publication.

[2] To end of 1940: iron ore £2,640,966; diamond £4,700,272.

TABLE 2. VALUE OF MINERAL PRODUCTION (IN £ STERLING) OF CERTAIN BRITISH COLONIES AND DEPENDENCIES DURING 1938.

Country	*Value*	*Principal Minerals with their Values*
Nigeria	2,100,000	Tin 1,685,000; gold 177,000; coal 180,000.
Gold Coast	6,267,000	Gold 4,811,000; manganese ore 908,000; diamond 548,000.
Sierra Leone	1,684,240	Diamond 818,925; iron ore 646,421; gold 216,793.
Kenya	633,388	Gold 499,601; soda 132,878.
Uganda	226,690	Gold 146,286; tin 78,483.
Tanganyika	712,730	Gold 588,679.
Northern Rhodesia	10,683,715	Copper 10,254,705.
Aden	120,971	Salt.
Ceylon	131,231	Graphite; excludes salt.
Palestine	330,000	Potash and bromine.
British Malaya	9,970,000	Tin 7,980,000; iron ore 920,000.
British Borneo (Brunei, Sarawak)	980,000	Petroleum 830,000; gold 130,000.
New Guinea (year June 1939)	1,700,000	Gold.
Fiji	632,000	Gold.
Trinidad and Tobago	2,765,680	Petroleum 2,654,492.
British Guiana	697,800	Bauxite 395,190; gold 226,337; diamond 74,273.

The information given above was supplied by the Mineral Resources Department of the Imperial Institute. Quarry products and salt are, in general, excluded. The following additional statistics have been derived from other sources.

Cyprus	1,495,000	Cupreous pyrite and concentrates 1,257,000, asbestos 88,291.
Ocean and Nauru Islands	850,000 (estimated)	Phosphates.
Bahrein Islands	2,050,000 (estimated)	Petroleum.
	44,030,435	

There was also a small production in other Colonies: for example, Bechuanaland (gold), Somaliland (salt), Swaziland (asbestos, gold), Papua (gold), Turks and Caicos Islands (salt).

These figures are but examples, and ignore the actual or potential value of Geological Surveys in other directions, notably in matters of water supply, a theme which Sir Edmund elaborated at some length. He stated that "Those who have not lived and worked in the tropical Dependencies do not, perhaps, realize the extent of country that suffers from the handicap of uncertain and seasonal rainfall. . . . Geological advice can in many cases provide a remedy and thus assist in a better distribution of the population and in the development of unused tracts of land."

As an example of one of the more indirect results of a Geological Survey, he remarked that in Nigeria the discovery of a coalfield resulted in the building of a direct railway linking the tin-fields with the coast and in the development of one of the best deep-water harbours in West Africa.

Referring to the Colonies of the British Empire as a whole, Sir Edmund said that "in very few cases has detailed systematic mapping of the standard adopted in Great Britain been attempted, and even in the countries with the strongest and longest established Surveys it can safely be asserted that the greater proportion of the geology shown on the published provisional geological maps is based on reconnaissance traverses. Shortage of staff and the absence of reliable topographical maps are two factors which have handicapped progress in systematic mapping. At the most, fewer than fifty geologists have been available, and at certain periods very many fewer, to deal with an area of about three million square miles—some thirty times the area of the Home Country. Compare this with the staff of over 5,000 trained geologists provided by the Soviet Government !" and, it may be added, with the fifty or so employed in Great Britain alone. As Sir Edmund remarked, the amount of money devoted to Colonial Geological Surveys is astoundingly insignificant in comparison with the benefits they have conferred upon the Empire. Accurate figures are not available, but they probably represent something of the order of a decimal of 1 per cent of the value of the mineral production.

The later part of Sir Edmund's address dealt with certain recommendations, put forward by members of the Institution of Mining and Metallurgy and fellows of the Geological Society, for securing for the Geological Surveys their rightful place in post-war Colonial development.

The meeting was then thrown open for general discussion, and a number of written contributions to the debate were received.

Sir Lewis Fermor, who spoke at some length, pointed out that the total area under the control of the Colonial Office is much smaller than Canada, and only of the same order of magnitude as the Indian Empire. Both these countries have found it advantageous to have unified Geological Surveys, yet each Colony, no matter how small, has its own Survey, or none at all; and this in spite of the fact that some of the Colonies occupy contiguous areas. He also directed attention to the fact that each Colony, no matter whether rich or poor, has to finance its own survey. This fact, combined with the lack of central co-ordination of the work of the several surveys, results in Colonial geological departments varying widely in size, whether expressed by number of personnel or the number of geologists per unit of area, and also in the salaries offered to geologists. Such conditions form a stumbling-block in the way of unifying the Colonial geological services. He suggested the grouping of the Colonies into larger units for geological purposes, and the establishment of a system whereby the emoluments of geologists were not directly related to the ability or otherwise of any particular Colony to pay an adequate salary. A move in this direction, he claimed, especially if it carried with it possibilities of promotion with transfer to other Colonies, would lead to an improvement in the morale of Colonial geological officers. It would also benefit not merely the officers concerned but, ultimately, the Colonies themselves.

A number of other points were raised during the course of the debate. One speaker directed attention to the tendency for the more ambitious and energetic geologists to leave government service to work for private mining companies, where better treatment and higher salaries were received; and another instanced the case of a highly successful Canadian mining company that thought it worth while to employ more geologists on its staff than the total number of government geologists in all our African Colonies.

A later speaker mentioned the Island of Trinidad, which, in spite of its valuable oil resources, has not been subjected to a general geological survey since 1860. As a consequence, when, during the present War, it became a base for American forces, and the question of water supplies for the northern part of the land arose, the Colonial authorities had no government geologist to advise them and had to turn for aid to the oil geologists. It was pointed out that the lack of a single government geological report on the geology of the oilfields there within the last thirty years indicated the lack of interest taken by the Colonial Department in these matters.

Sir Thomas Holland, in a written communication, made the following points. He disposed of the suggestion that the geological mapping of the Colonies might be nearing completion by pointing out that so long as geological science continues to progress and specialize, the geological map will never be finished. So long as mineral values continue to change, as they have done in the past, and no doubt will in the future, for a variety of reasons, so often, too, will parts of the geological map need revision. Sir Thomas also directed attention to the desirability that the information accumulated during the course of the Colonial Geological Surveys should be published in some systematic and organized way, so that it might become readily accessible to the outside geological world for reference and, if necessary, criticism.

Another speaker mentioned the importance of geophysical prospecting as an essential adjunct to a Geological Survey. This, he claimed, is insufficiently recognized, and Colonial Surveys should be adequately equipped in this respect, both instrumentally and in respect of suitably trained staff.

Another contributor to the debate made an eminently practical and valuable suggestion in connexion with the possibilities of air survey in the development of the Colonies. He mentioned that the R.A.F. has accumulated a large staff, highly trained in the modern technique of air photography, and in the interpretation of air photographs, the use of which in prospecting and the interpretation of geological structure is well recognized; in passing, it may be mentioned that a number of geologists are actually employed on this staff. It is incumbent on the Government, he suggested, and in particular the Colonial Office, when the War ends, to secure the service of these expert technicians and their

equipment for use in the development of the Colonies.

At the conclusion of the meeting the following resolutions were proposed and carried unanimously:

(1) That this Joint Meeting of the Geological Society of London and of the Institution of Mining and Metallurgy welcomes the attention now being given to the resources of the Colonial Empire and desires to stress the importance of Geological Surveys in the well-being of the Colonies, especially for the development of mineral resources and in connexion with water supply, public works, soil conservation, agriculture and forestry.

(2) That this Meeting views with concern the progressive deterioration of status of certain Colonial Geological Surveys and the discouraging conditions under which these Surveys are now functioning. It is also of opinion that Colonial Government Departments do not fully appreciate the practical value of geology to the community and the need for maintaining the individuality of the Surveys, under the direction of competent and experienced geologists.

(3) That this Meeting advocates: (*a*) the appointment by the Colonial Office of a Colonial Geological Surveys Advisory Board, (*b*) the appointment to the staff of the Colonial Office in London of a scientific Director-General of Colonial Geological Surveys, who should report periodically to the Advisory Board and should inspect the work of the Colonial Geological Surveys from time to time.

(4) That this Meeting urges that the deputation appointed by the Councils of the Geological Society and the Institution of Mining and Metallurgy jointly should wait upon the Secretary of State for the Colonies and submit their views with the object of increasing the scope and fostering the welfare of the Colonial Geological Surveys as an essential part of the post-war development programme for the Colonial Empire.

We are informed that the proposed deputation has since been favourably received by the Secretary of State for the Colonies.

While it seems clear that the action taken was well justified, in fairness to the Colonial Office it should be stated that a certain amount of attention has recently been given to the matter. Following on the passing, in 1940, of the Colonial Development and Welfare Act, a Colonial Research Committee was appointed, in June 1942, to advise upon the expenditure of the annual sum of £500,000 provided by the Act of 1940 as provision for Colonial research, and to assist in co-ordinating the wh. le range of research in Colonial studies. This Committee recently published its first progress report (see NATURE, **153**, 119; 1944). In this report it is pointed out that Geological Surveys would come within the Committee's purview, and it is also noted that they do not at present exist in certain Colonies. The Committee further directs attention to the fact that mineral development of Colonies is impossible without accurate topographical surveys. A grant of £7,000 to enable the Geological Survey of British Guiana to be carried on on a proper basis is recorded in this report; and, according to *The Times* of December 31, 1943, a further grant of £32,000 has been made for geological survey work in Nigeria.

The timely action taken by the Geological Society and the Institution of Mining and Metallurgy will, no doubt, serve a useful purp se in impressing on the Committee the urgent need for further action in this direction.

V. A. EYLES.

CANCER RESEARCH IN BRITAIN DURING 1942–1943

THE twentieth annual report of the British Empire Cancer Campaign was presented recently at a meeting in London. In proposing the adoption of the report, Prof. E. C. Dodds dealt in a general way with the difficulties of presenting the results of scientific research on cancer to the public, and with the complexity of modern experimental biology. He made particular reference to the success obtained in the treatment of cancer of the prostate with synthetic œstrogens.

Clinical

Recently American clinicians have obtained good results in the treatment of cancer of the prostate with œstrogenic substances. Similar results have now been seen in Great Britain. In one case treated at the Middlesex Hospital, the results of the American observers have been completely confirmed in the twelve months that the patient has been under treatment. Seven cases have been treated with diethyl stilbœstrol at the Royal Cancer Hospital by Dr. J. Watkinson, in collaboration with members of the honorary staff. In five of these cases there was evidence of secondary deposits in bone and an increase in the acid phosphatase in the blood serum. In these five cases the treatment produced some regression of the primary growth, a fall in the serum acid phosphatase and a reduction in the pain due to metastases. In one patient regression of a lymph node deposit was observed. Two cases appeared to derive no benefit from the treatment, but on the whole the work is most promising.

The Clinical Cancer Research Committee gives an analysis of details of more than a thousand cases of intrathoracic cancer. The analysis in general is in agreement with existing knowledge. The incidence is high among painters, decorators, engineers and mechanics. It is low among clerks and typists. Although 74 per cent of the patients consulted a doctor within three months of the onset of symptoms, 90 per cent died within a year of the time when diagnosis was made.

Experience gained with the million-volt X-ray installation at St. Bartholomew's Hospital indicates that high-voltage therapy is particularly effective in the treatment of cancer of the rectum.

Carcinogenic Agents

Workers at the Royal Cancer Hospital have found that 1 : 2′-diamino 1′ : 2-dinaphthyl, which inhibits growth but has not produced tumours at the site of injection or application, induces multiple adenomas of the lung in mice. The substance thus has a remote carcinogenic action. Russian and French workers have obtained tumours in mice remote from the site of injection of extracts of human lung and liver. Many tumours have occurred at the site of injection of extracts of human organs, but such tumours have generally appeared at least twelve months after the beginning of treatment. The agents present in human organs appear to be weak and slow in action. As yet it has been impossible to ascertain before test whether a particular organ will give a carcinogenic extract, so that progress in this field has been slow.

Prof. H. N. Green and Dr. F. Bielschowsky have made further studies on the action of the carcinogenic insecticide, 2-acetylaminofluorene. When fed to male rats, this substance produces tumours of the liver

similar to those produced by 'butter yellow'. In female rats, it produces adenocarcinomas of the breast, although the substance itself does not appear to be œstrogenic. No other insecticides or phenothiazine derivatives have been found to have carcinogenic activity, but phenothiazone is toxic when fed in small amounts over a long period.

3 : 4-Benzpyrene was first isolated from coal tar ten years ago. Dr. I. Berenblum and Dr. R. Schoental, of Oxford, have recently investigated the carcinogenicity of fractions of coal tar separated by chromatographic methods. They find that the fraction containing the benzpyrene is less active than certain other fractions in producing cancer on the skin of mice and rabbits. American workers during the past year have published results showing that although benzpyrene is rapid in its action, the dose required to induce tumours in mice is much larger than the corresponding dose of 1 : 2 : 5 : 6-dibenzanthracene (W. R. Bryan and M. B. Shimkin, *J. Nat. Cancer Inst.*, 3, 503 ; 1943). In attempts to obtain new types of tumours in fowls at the Glasgow Royal Cancer Hospital, injections of benzpyrene and methylcholanthrene have failed to produce tumours. On the other hand, many tumours have been induced in chickens with dibenzanthracene. Experiments carried out at Sheffield suggest that cats are resistant to the action of benzpyrene and methylcholanthrene.

Dr. J. W. Orr has applied methylcholanthrene to the nostrils of mice from a strain (I.F.S.) in which breast tumours do not normally occur. No lung tumours were found, but of twenty-nine female mice treated in this way eighteen developed mammary cancer.

Metabolism of Carcinogenic Hydrocarbons

Dr. I. Berenblum and Dr. R. Schoental, working at Oxford, have found that benzpyrene is converted into 8-hydroxybenzpyrene, and that 1 : 2-benzanthracene is converted into 4'hydroxy 1 : 2-benzanthracene in the intestinal tracts of mice and rats. These phenolic substances which are formed are not carcinogenic. The Oxford workers have collaborated with scientific workers of the Royal Cancer Hospital in studying the growth-inhibiting power of these metabolism products and their derivatives. The metabolism products themselves have no growth-inhibiting activity, although some hydroxy derivatives, such as 4'hydroxybenzpyrene, are active growth-inhibitors. Some methyl derivatives of the metabolism products can inhibit the growth of tumours. The active substances of this type are all monomethoxy compounds, such as 4'methoxy 1 : 2-benzanthracene and 8-methoxy benzpyrene. The dimethoxy derivatives of carcinogenic hydrocarbons appear to be devoid of growth-inhibiting activity.

Bone Tumours in Mice

Some years ago Mr. F. C. Pybus and Dr. E. W. Miller of Newcastle-upon-Tyne developed a strain of mice in which bone tumours including sarcomas frequently occurred. In 1936, about one quarter of the mice which died had palpable osteomata or sarcomata, but since then the incidence of bone tumours has declined although the mice have been inbred. Over a ten-year period 21 per cent of females and 7 per cent of males of this strain died with bone tumours. The difference in incidence in the sexes suggests that œstrone might have some influence on the development of these tumours. Dr. J. W. Orr has studied the effect of œstrone on the histology of the bones of mice. The bones of female mice of this 'Newcastle bone tumour' strain are unusual in that there is a considerable amount of medullary bone and a mosaic appearance in the cortex. The bones of spayed females of this strain resemble those of normal mice. Treatment of mice of other strains with œstrone causes osteoclastic changes, including both resorption and production of bone. The mice of the Newcastle bone tumour strain are exceptionally susceptible to the action of œstrone. A sex hormone, in addition to other unknown factors, probably plays some part in causing the bone tumours that are found in this special strain of mice.

Filterable Agents

Experiments carried out at the Middlesex Hospital show that injection of either proflavine or 5-aminoacridine into the breast tissue will localize the Rous sarcoma virus. The localization of the virus leads to the formation of a tumour at the site of injection of the acridines. Kieselguhr is a localizing agent, but is much less effective than the acridine compounds. Methylcholanthrene is a very feeble localizing agent. The effect is probably governed by the type of tissue reaction resulting from the injection. The acridine compounds have a mild toxic action and cause proliferation of muscle nuclei.

Only a few of the topics dealt with in the report have been mentioned, but it is clear that progress has been made in the face of difficulties and many new facts have been brought to light during the year under review. With its coming of age, the British Empire Cancer Campaign is to be thanked for the way it has raised funds to support cancer research and for the care with which it has organized and correlated the efforts of many scientific men working in fields directly and indirectly bearing on the subject.

E. BOYLAND.

GYROSCOPIC PRINCIPLES AND APPLICATIONS

GYROSCOPY, since it belongs to classical mechanics, tends to be neglected by the modern physicist. We have now to depend on the engineers and applied physicists to maintain the teaching of the subject. Its applications cannot be ignored; in the development of modern applied science we find many extremely important applications of gyroscopes; and in the increased use of bodies rotating at angular speeds that are being continually increased from year to year, we find gyroscopic effects that must be taken into account in the design of the supporting structure whenever the rotating body, whether it be engine, wheel or propeller, has the direction of its axis of spin altered. When a motor-car turns to the left, the spin of the engine causes a transfer of load from rear axle to front axle, and the spin of the wheels gives a transfer of load from inner to outer wheels. When a single-engined aeroplane turns to the left, the nose tends to dip ; when the turn is to the right, the gyroscopic effect tends to raise the nose. When a twin-engined plane, with propellers turning in opposite directions, alters course, the leading edge of one wing tends to dip and the leading edge of the other tends to rise, so that additional stresses on the structure are intro-

duced. Jet propulsion will lead to the removal of the gyroscopic action of the propellers, and perhaps also to the removal of much of the gyroscopic action of the engines.

The subject is a difficult one; the mathematical treatment is not easy, and the translation of the mathematical results into application requires the powers of both mathematician and engineer. Prof. C. E. Inglis has both qualifications, and in the thirtieth Thomas Hawksley Lecture to the Institution of Mechanical Engineers*, he has given an excellent account of the theory of gyroscopy, and has detailed several practical demonstrations and applications, some new, all interesting. Usually the subject is approached from the idea of angular momentum, and the couple required to change the direction of this vector quantity. Prof. Inglis begins in a simpler way: if a point P is travelling with a speed v along a radius vector rotating with angular speed Ω, then P must have an acceleration $2v\Omega$ in a direction perpendicular to the radius vector. If now a gyroscope is spinning about a horizontal axis, and is being forced to precess about a vertical axis, every point in the upper half of the gyroscope requires an acceleration in a direction parallel to the axis of spin, and every point in the lower half requires an acceleration in the opposite direction. Hence the precession of the gyroscope about a vertical axis requires a couple about a horizontal axis perpendicular to the axis of spin. The simple working rule follows, that the axis of spin tends to turn towards the axis of the applied couple.

Excellent demonstrations by Prof. Inglis illustrate these points. A belt is running with velocity v between two vertical pulley wheels mounted on a horizontal platform that can rotate about a central vertical axis with uniform angular velocity Ω. Each horizontal part of the belt has to develop a horizontal acceleration $2v\Omega$, so that there is a transverse parabolic bowing of the belt, the upper part to one side, the lower part to the other side. A second demonstration of the same effect is given by means of a gyroscope, the disk of which is composed of several layers of paper. If the axis of spin of the gyroscope is horizontal, and the axis of the applied couple is vertical, the disk becomes warped about a horizontal axis perpendicular to the other two axes, and not about the axis of the applied couple.

In the next demonstration, a gyroscope spins about a horizontal axis, its axial supports being carried by a frame that is free to rotate, about a horizontal axis perpendicular to the axis of spin, in a second frame that is free to rotate about a vertical axis. A couple is applied, by means of a weight suspended from a point in the first frame, on the axis of spin produced. The axis of spin remains horizontal, but the gyroscope precesses about a vertical axis. In the demonstration, the gyroscope was a powerful one, of polar moment of inertia 25 lb.-ft.^{2} and of angular speed 3,000 r.p.m., and the couple of 150 lb.-ft. was produced by the weight of a man suspended at a point one foot from the centre point of the gyroscope; the man was carried through a complete rotation about a vertical axis in about $10\frac{1}{2}$ seconds. Hurrying the precession raised the man, retarding the precession lowered him. When the precessing frame of such a gyroscope hits a stop and is brought to rest, the gyroscope begins to tilt over; a very considerable couple is developed tending to remove the resistance to precession; this couple reaches a maximum at a tilt of about 35°, and decreases to zero at a tilt of 90°.

The general equations of motion of a precessing gyroscope are worked out in a mathematical appendix, and several important deductions are made. The frequency of nutation, in which there is a periodic interchange of kinetic energy between tilting and precession, is deduced, and emphasis is laid on the importance, for great stability, of a high natural frequency. In the paper a description is given of a new form of gyroscopic vibration damper, originated by Dr. R. N. Arnold, by means of which excessive chatter in a heavy armour-plate planing machine has been suppressed, the frequency of the gyroscope being tuned to the frequency of the chatter, and suitable fluid damping being applied.

The gyroscopic action of a pair of wheels of a locomotive or motor-car when the vehicle is rounding a curve is worked out; the load transferred from inner rail to outer rail for a typical pair of locomotive wheels and axle moving in a typical railway curve is shown numerically to be negligible. It is also shown that if one of the pair of wheels drops through a small distance at a rail joint on a straight part of the line, the resulting precession about a vertical axis is by no means negligible, and the practical conclusion is drawn that rail joints should be placed side by side, and not staggered.

Gyroscopic stabilization of a monorail truck is considered very fully, both in a second mathematical appendix and in descriptions of arrangements that lead up to the Brennan monorail stabilizer. The gyroscopic ship-stabilizer and the gyrocompass are treated in as simple a manner as the subjects will permit. The paper concludes with an explanation of the stability of a spinning-top. Emphasis is given throughout to the principle, so valuable when appreciated and properly applied, that a spinning body can be given complete stability by hurrying the precession; the child's top rises to the sleeping vertical position because frictional forces at the peg hurry the precession; and the same principle leads directly to the realization of an artificial horizon for the navigator, and of a horizontal sighting platform for the bomb aimer. ROBERT C. GRAY.

* "Gyroscopic Principles and Applications". By Prof. C. E. Inglis. Being the Thirtieth Thomas Hawksley Lecture to the Institution of Mechanical Engineers, delivered on November 19, 1943. (Institution of Mechanical Engineers, Storey's Gate, London, W.C.1.)

OBITUARIES

Dr. H. A. Mess

HENRY A. MESS, reader in sociology in the University of London, whose death took place early in January, was one of the few men who have been fortunate enough to combine the academic life, which he loved, with very wide experience in the field of social administration. He came into the university world at a later age than is usual, but all his previous work was, in a sense, a preparation for his main interest and provided him with an inexhaustible supply of material on which to draw for his study of the structure of society.

Dr. Mess was born in 1884 in Stoke Newington and educated at Bancroft School, Woodford, but, owing to a decline in the family fortunes, he was not able to go to Oxford as he had hoped. While earning his living as a clerk in an insurance office, he attended evening classes and, in 1905, took first-class honours in modern languages as an external student of the

University of London. All his spare time was given to teaching literature at the Mansfield House University Settlement in Canning Town, where he found himself becoming so absorbed by the social problems of the neighbourhood that, in 1912, he became secretary to the Settlement, a post which he held until 1919. This experience coloured his whole life and determined his future work for, on removing to the Settlement, he was immediately plunged into the distress connected with a great dock strike, and his first book, "Casual Labour at the Docks" (1916), was based on material collected in Canning Town. The conditions with which he was brought into such close contact convinced him of the need for a careful study of social organization if any constructive reform was to be achieved, and this remained the chief preoccupation of his life.

Further experience, first as social studies secretary of the Student Christian Movement, later as lecturer in social science to the Lancashire and Yorkshire Congregational Union, gave Dr. Mess greater opportunities for gathering detailed knowledge of social conditions and, after a period at the London School of Economics during which he wrote his "Factory Legislation and Administration", he began the work which was to prove his most outstanding achievement. In 1925 he was appointed director of the Bureau for Social Research for Tyneside and later director of the Tyneside Council of Social Service, and for ten fruitful years he identified himself with the life of a region that was suffering all the incalculable misery of prolonged industrial depression. True to his belief in the need for greater knowledge, he was not content to initiate and foster innumerable efforts to preserve and develop the community life of the area; he also conducted a social survey, published as "Industrial Tyneside", which is a model of its kind.

In 1935 Dr. Mess was appointed reader in sociology at Bedford College (University of London), and for the first time had the leisure to devote himself more fully to research; but he was by no means cut off from other activities. He sat on many advisory bodies, acted as University Extension lecturer and gave many broadcasts, the most notable of which was a series of talks on "Social Groups in Modern England", which was later published in book form. In 1942 the College gave him part-time leave of absence to enable him to act as director of studies to the National Council of Social Service, and at the time of his death he was engaged in a number of extremely important inquiries, in which the combination of sociological technique with his wide knowledge of contemporary economic and social conditions was of inestimable value.

By temperament, Mess belonged to that breed of Nonconformist Liberal whose contribution to social reform in Great Britain has been so striking and, indeed, through his mother's family he had direct links with the early Independents. He was a sincere Christian with a profound belief in the dignity and powers of the common man, given the right social environment. It was from this faith that all his work drew its inspiration. As a sociologist, he was just beginning to see his way clear, and there is no doubt that, had he lived, his wide knowledge and humane sympathies would have enabled him to make a real contribution to this youngest of university disciplines. English sociologists can ill afford to lose so valuable a member of their small band.

GERTRUDE WILLIAMS.

Major H. J. L. Beadnell

HUGH JOHN LLEWELLYN BEADNELL died suddenly on January 2. He was born in 1874 and was educated at Cheltenham College, King's College (London) and the Royal College of Science. He had a long and vigorous career, and his name is linked above all with the geology and water resources of the Libyan Desert. He joined the Geological Survey of Egypt in 1896, and his early work included the geology of the Abu Roash dome near the Pyramids of Giza: soon, however, he was sent westward to the Libyan oases of Farafra, Dakhla, and Baharia, and then to the Faiyum. His report on the last of these was a remarkable achievement, and it provided a solid basis for the specialized work of those who followed more than twenty years later with advantages of transport and equipment which were unheard of in his day. From his Faiyum investigations, moreover, came the discovery, in which C. W. Andrews of the Natural History Museum shared, of the highly important Eocene and Oligocene mammalian remains (Eosiren, Moeritherium, Palæomastodon, Arsinoitherium and others) which are known to palæontologists throughout the world. In 1905 he investigated the relations of the Eocene and Cretaceous beds between Esna and Aswan, in Upper Egypt.

In 1906 Beadnell's interest in the Libyan oases took him into the scheme for the reclamation of Kharga oasis, and he left Egyptian Government service. He was concerned with this project, which did not realize expectations, until 1910, and he published the well-known book "An Egyptian Oasis" in 1909.

The next phase of his life was varied, and typical of him. He went ranching in British Columbia (1912–15), enlisted in the Artists Rifles in 1916, served with the Egyptian Expeditionary Force (1916–19), and completed his service with the acting rank of lieutenant-colonel: he was mentioned in dispatches and received the Order of the Nile. After the War he was engaged in the search for oil, was surveying in Central Sinai and on the Red Sea coast during 1921–25 (in Egyptian Government service once more) and wrote "The Geology of the Red Sea Coast between Qoseir and Wadi Ranga" (Petroleum Research Bulletin No. 13, 1924). Two years later his delightful book "The Wilderness of Sinai" was published.

In 1927 Beadnell returned to official work in the Libyan Desert and for two years he was actively employed, especially with the work on wells in remote parts of the desert. Too little has been written of what he achieved in those two years and in his last period in the Libyan Desert, during 1930–32, when he was resident engineer of the Qattara Depression hydro-electric project of the Egyptian Government. The scheme aimed at running water from the Mediterranean to turbines at a site below sea-level in the depression.

From about 1932 Beadnell was seriously ill and spent much of his time in London: active still, he maintained his lifelong interests and took up gemmology. His last years were clouded by the death of one of his two daughters, then of his wife, who had been his companion since the early days in Egypt (they married in 1904). In 1940 he was engaged by the War Office with the rank of temporary major in the Royal Engineers, which he held at the time of his death.

In addition to his two books and to his official

reports, Beadnell contributed to scientific publications, and especially to the *Geographical Journal*. He was awarded the Barlow-Jameson Fund of the Geological Society of London in 1904 and received the Cuthbert Peak Grant of the Royal Geographical Society in 1931. K. S. SANDFORD.

Dr. Birkett Wylam

BIRKETT WYLAM, chief inspector for Scotland under the Alkali, &c., Works Regulation Act and Rivers Pollution Prevention Acts, died suddenly at his home in Edinburgh on January 15. While Dr. Wylam had not been in his usual vigorous health for some time, the news of his untimely death came as a shock to his many professional friends.

A native of County Durham, Dr. Wylam was a graduate of the University of Durham, where he took the degrees of B.Sc. in 1921, M.Sc. in 1922 and Ph.D. in 1925. He became an associate of the Royal Institute of Chemistry in 1924 and was elected to the fellowship in 1935. He was an active member of the Council of the Institute during 1938–40, and was a prominent figure in the Edinburgh Section, of which he was chairman. He also took an active interest in the Society of Chemical Industry. In 1936 he became a member of the Institution of Chemical Engineers.

Dr. Wylam began his professional career as research chemist to Morton Sundour Fabrics, Ltd., and later was research chemist and process manager at Scottish Dyes, Ltd. (I.C.I.), Grangemouth. He left this post to take up his official duties with the Department of Health for Scotland in 1931. During the War of 1914–18 he served with the Royal Garrison Artillery in France.

I have been privileged to know Dr. Wylam for some eight years, during the last five of which I have been his colleague. He was a delightful person to work with, always thorough, sympathetic and helpful. He was a fair man, his standards were high, and he was incapable of being mean. His chief interest was in doing things, and an idea had no sooner crystallized in his mind than the machinery was set in motion to effect its realization. He never sought praise; it was sufficient for him to experience the pleasure of a job well done.

In his dealings with the chemical industry in the execution of his official duties he earned the respect of all as a competent chemical engineer, and he carried into this sphere his personal characteristics of fairness, high standards, and ever-readiness to help. For reasons of national security I cannot give details of his war-time activities; it is sufficient to say that his whole energy was directed into channels calculated to shorten the duration of the present conflict.

Dr. Wylam truly lived and enjoyed every moment of his life, at work, at home and at play. His hobbies were all constructive as well as artistic. He had a wide range of engineering and woodworking tools, which he put to no mean use. He was a keen photographer, a collector of commemorative medals, and a very wide reader. Science in Scotland has lost a man who, by virtue of his wide practical experience and acute mental alertness, was at his prime. To Mrs. Wylam and her children we offer our most sincere sympathy. JOHN HAMILTON.

WE regret to announce the following deaths:

Dr. L. H. Baekeland, the distinguished plastics chemist and inventor of 'Bakelite', on February 23, aged eighty.

Mr. H. H. Brindley, fellow of St. John's College, Cambridge, and during 1926–34 University demonstrator in zoology, on February 19, aged seventy-eight.

Prof. J. W. H. Eyre, emeritus professor of bacteriology in the University of London, on February 17, aged seventy-four.

Prof. Yandell Henderson, professor of applied physiology at Yale University, on February 18, aged seventy.

Mr. J. Reid Moir, F.R.S., president of the Ipswich Museum, on February 24, aged sixty-four.

Prof. H. F. Newall, F.R.S., emeritus professor of astrophysics in the University of Cambridge, on February 21, aged eighty-six.

Dr. E. O. Ulrich, formerly geologist in the U.S. Geological Survey, known for his work in invertebrate palæontology, aged eighty-seven.

Mr. S. E. Winbolt, formerly of Christ's Hospital, Horsham, who was an authority on Roman antiquities in Great Britain, on February 16, aged seventy-six.

NEWS and VIEWS

Edinburgh Medical Men and the Great Adventure

THE spirit of adventure as it has been exemplified by graduates of the University of Edinburgh was the theme selected by Prof. James Ritchie for his 'Promotor's' address at the Medical Graduation at the University of Edinburgh last July. It was, Prof. Ritchie pointed out, the Edinburgh medical graduate Mungo Park who discovered and traced the greater part of the course of the River Niger. Another medical student, Laing, discovered its source. Yet other Edinburgh medical men completed the Niger adventure, for Oudney discovered Lake Chad and Baikie led the last Niger expeditions sent out by the British Government. All these pioneers died in Africa. But, even before Park's day, men from the University of Edinburgh had been active in Africa. James Bruce re-discovered the sources of the Blue Nile, while Joseph Thomson, a pupil of T. H. Huxley, has been described as the last, and one of the most successful, of the great geographical pioneers in Africa. Other Edinburgh medical men have carried the spirit of adventure to geographical discoveries in India, Australia and America, and these men studied at the same time the natural history of the lands wherein they pioneered. On the seas the spirit of adventure is exemplified by Scoresby, the Whitby lad who became a world authority on the life of whales. To the Edinburgh naturalists Sir John Richardson, Harry Goodsir and John Macgillivray, the Franklin Arctic expedition owed much.

No doubt the graduates of Edinburgh or of other universities will be interested to learn that Edward Forbes, who founded the science of oceanography, left that University in his ninth year as a medical student without a degree, to return fourteen years later to do brilliant work as its professor of natural history. Wyville Thomson, another medical, also left without a degree, but because his health was not

good: twenty years later he became professor of natural history and planned and carried out the *Challenger* expedition. Another great oceanographer, Sir John Murray, continues the list of Edinburgh medicals who left without completing their degrees, a list which W. S. Bruce, who led the Scottish National Antarctic expedition, continues into the present century. Here is a record which will inspire the Edinburgh graduates of to-day, secure in the knowledge that they have got their degrees, to even greater achievements. As medical men they will do well to preserve in their minds Prof. Ritchie's reminder that there are Dark Continents of disease and suffering in all grades of modern society. The discovery, investigation and removal of these is especially the job of the modern medical man.

Mathematics as a Compulsory Examination Subject

MR. D. BROWNLIE, who is an organic chemist and chemical engineer, has published a pamphlet strongly advocating the abolition of compulsory mathematics in university matriculation examinations, even for degrees in engineering or science. He claims that "the very great majority of candidates, say about 90–95 per cent, have no particular aptitude in the subject of mathematics, which is almost universally detested. . . . Actually, mathematical proficiency above the normal is no indication of superior intelligence. . . . It would, in fact, not be difficult to make out quite a good case for the contention that in a considerable proportion of cases proficiency in mathematics is actually a sign of mental deficiency. . . . My experience with Euclid or geometry, or whatever it is now termed, had the natural result, as in the case of most other students, of regarding it as a pest to be learned by heart and forgotten completely as soon as the Matriculation examination was over." At a time like the present, when the educational system of Great Britain is being reconstructed, there is a place for a careful inquiry into the validity of the claims for the traditional subjects and methods of instruction. The use of wild and exaggerated language is not helpful in such an inquiry. A more useful step is the attempt, now being made by a committee representing all English School Certificate examining bodies and also the Mathematical Association, to provide an alternative course of mathematics, more closely allied to its applications, which can be followed by those who find the present school mathematics too abstract.

Refugees in Great Britain

POLITICAL AND ECONOMIC PLANNING (P E P) in a recent broadsheet (No. 216, January 14, 1944) gives a useful review of the present position of refugees in Britain and of the changes which have taken place during the War and since the appearance of Sir J. H. Simpson's report "The Refugee Problem" in 1939. The present number of civilian refugees is estimated at 139,430, including 50,000 Germans and Austrians, and 20,000 Allied seamen, a total which differs from that of the Prime Minister's statement of April 7, 1943, in allowing for those who have left or died since the beginning of the War. Considerable progress has been made in utilizing the services of aliens with special professional, technical or academic experience. According to the Minister of Labour's statement of September 23, 1943, shortly after the 1941 registration 82·5 per cent of the men and 60 per cent of the women were in employment, and since 1941 the opportunities open to aliens to engage in war-work have increased, so that the number who now remain unemployed is negligible.

The economic absorption of pre-war refugees has broken down their isolation, removed prejudices and enabled them to become acquainted with the British way of life. By and large, they have proved a valuable element in society: they have made contributions to the national life in industry, in the universities, in the arts and in science, and have acquitted themselves well during the War. The number of those who will wish to remain in Britain is estimated as roughly 40,000, a figure which is much smaller than in other countries before refugee emigration began in 1933. This number should be absorbed without difficulty after the War: a full employment policy for Great Britain should mean the disappearance of the refugee problem as we knew it before the War; but the refugees must be given a fair chance of sharing both the rights and obligations of British citizens.

Technological Museum of New South Wales

THE annual report of the curator of the Technological Museum of New South Wales for the year ended December 31, 1942, states that the scientific work of the Museum has been placed on a war footing without necessitating any reorganization of laboratory work. Chemical investigations of national importance have included the recovery of by-products from charcoal burning, dyeing of khaki cloth, preparation of coloured flashes and composition of flash powders and smoke screens from motor exhausts, fireproofing paper and 'Cellophane' gas respirators, Australian essential oils as mosquito repellents, rot-proofing of sandbags, strength of laminated plastics for aircraft, production of lactic acid and lactates from waste whey, and sources of quinine and similar alkaloids in Australia. Work has also been done on synthetic wax, fire-proofing fabrics for camouflage purposes, synthetic rubber from acetylene, production of drugs and natural dyes from Australian plants, camouflage materials, especially paint, wax from sugar-cane, and the relative humidity for controlling the development of moulds likely to attack silk parachutes in Queensland. Botanical investigations into the cultivation of the tung oil tree in Australia, as well as on suitable Australian fibres to relieve the shortage of imported material, and the important research on the cytology of the eucalypts and other genera, were continued. Much time has been devoted to the study of rot-proofing problems in the preservation of jute hessian, canvas and manilla, hemp and cotton rope and to the waterproofing and rot-proofing of canvas duck. Lists of lectures, etc., delivered, papers read before scientific societies, exhibits and publications are included.

Performance of Generating Plant

A PAPER read in London on February 3 before the Institution of Electrical Engineers by R. W. Biles and G. W. Maxfield reviews the performance of a group of generating stations over a five-year period, commenting upon coal qualities, thermal efficiency, analysis of the different classes of breakdown with deductions as to probable operating life between breakdowns, plant availability and the effects of loading. The plant under review is divided into three groups: pre-1930, 1930–1937 and 1938–1942.

From the results, curves for maximum probable availability are deduced. The suggestion is made that 'operating efficiency' should be calculated on a uniform basis and included in station records. The need for an overall standard by which the performance of generating stations can be judged is discussed, and the term 'standard merit', based upon operating efficiency and plant availability, is suggested.

It is concluded from the analysis that pre-1930 plant should not be operated at above 45 per cent average running plant load-factor if good availability is to be consistently maintained; marked improvements are to be noted in availability of the most recent plant installed since 1938 at 80 per cent average running plant load-factor; the lower breakdown rate per plant item of the pre-1930 group is notable when compared with that of the later plant groups. Good quality and grading of fuel supplies are needed, particularly for the pre-1930 plant, if maximum outputs are to be obtained. With larger units of plant, greater outputs between breakdowns have been possible: but it is not safe to conclude that larger units still would be to the general benefit of the supply industry. Size of unit required is related to the load curves and security needs.

Economic Rating of Motors and Transformers

IN a paper read by Mr. D. J. Bolton before the Institution of Electrical Engineers on December 2, physical and economic ratings of motors and transformers respectively are compared, and the scope and limits of economic choice are discussed and illustrated. A method of economic selection is proposed through the use of larger standard machines, and a technique is developed for investigating the economy of changes in rating. Tables of data and results are given at the end of the paper, and the methods employed in these tables are explained in some detail. The results are expressed in the form of an 'economic advantage' obtainable through under-running or over-running, and show the former to be highly advantageous in a large number of cases. Methods of implementing the results are discussed.

Canadian Mortality in War Years

ACCORDING to an annotation in the September issue of the *Statistical Bulletin*, the health of the Canadian people has remained at a very favourable level during the four years of the present War, the mortality in this period being the lowest on record. The improvement in mortality has been particularly marked in the diseases most prevalent among the young. Not only has the death-rate decreased among the communicable diseases of childhood, but also there has been an increased fall in the mortality among the large number of young adults in training camps. Diarrhœa and enteritis, which have always been important causes of death among Canadian children, have also shown considerable improvement in recent years. The rate of decline in tuberculosis is illustrated by a new minimum of 47·1 per 100,000, which is about one fifth below that for the period 1934–36. In contrast with the catastrophic influenza epidemic towards the close of the War of 1914–18, there has so far been no cause for serious concern, although there was a mild epidemic of influenza in Canada late in 1940 and early the following year, the favourable result being mainly due to the use of serum and chemotherapy in the treatment of pneumonia. Chemotherapy has also succeeded in reducing the mortality from appendicitis and the diseases incidental to child-bearing. On the other hand, there has been an increase in the mortality from cancer, diabetes, diseases of the heart and arteries, and from accidents.

Announcements

PROF. A. R. TODD, Sir Samuel Hall professor of chemistry in the University of Manchester, has been appointed professor of organic chemistry in the University of Cambridge.

PROF. ANTON J. CARLSON, chairman of the Department of Physiology in the University of Chicago, has been elected president of the American Association for the Advancement of Science.

THE title of professor emeritus of bacteriology in the University of London has been conferred on Sir John Ledingham, on his retirement from the professorship of bacteriology at the Lister Institute of Preventive Medicine. The degree of D.Sc. has been conferred on Mr. B. Prasad (University College), Dr. E. C. Barton-Wright (Birkbeck College and Chelsea Polytechnic), Mr. A. G. McDonnell Weddell (St. Bartholomew's Hospital Medical College), and Mr. George King.

THE Edison Medal for 1943 of the American Institute of Electrical Engineers, one of the highest honours in the field of electrical science and engineering, has been awarded to Dr. Vannevar Bush, president of the Carnegie Institution of Washington and director of the Office of Scientific Research and Development of the U.S. Office of Emergency Management, "for his contribution to the advancement of electrical engineering, particularly through the development of new applications of mathematics to engineering problems, and for his eminent service to the nation in guiding the war research program". Dr. Bush has also just received the Holly Medal of the American Society of Mechanical Engineers, for his work as a leader of engineering education and in scientific research, and in particular for his work on calculating machines.

OWING to the generosity of the Rockefeller Foundation of New York, which has for the fourth year in succession provided a grant for the purpose, the Royal Society is in a position to give some assistance to scientific societies and associations which, as a result of war conditions, are experiencing financial difficulties in the publication of scientific journals.

THE following appointments to the Colonial Service have recently been made: E. Dixon to be veterinary officer, Nigeria; W. J. J. Filkins to be physiological laboratory superintendent, Uganda; J. S. Groome to be forest officer (temporary), Tanganyika; G. W. P. Streeton to be deputy government chemist, Jamaica.

ERRATA.—We are asked by Dr. A. Hunter to make it clear that the experiments on exposure-time effects in photographic photometry attributed to him in NATURE of February 26, p. 242, were planned and carried out by Prof. W. M. H. Greaves, Astronomer Royal for Scotland. Furthermore, the microphotometers he described at the symposium give intensity traces direct, not merely density records, as stated.

LETTERS TO THE EDITORS

New Types of Optical Glass

IN view of the interest shown in new optical glasses recently produced in Great Britain and in the United States, we wish to summarize the present position and to indicate probable lines of development.

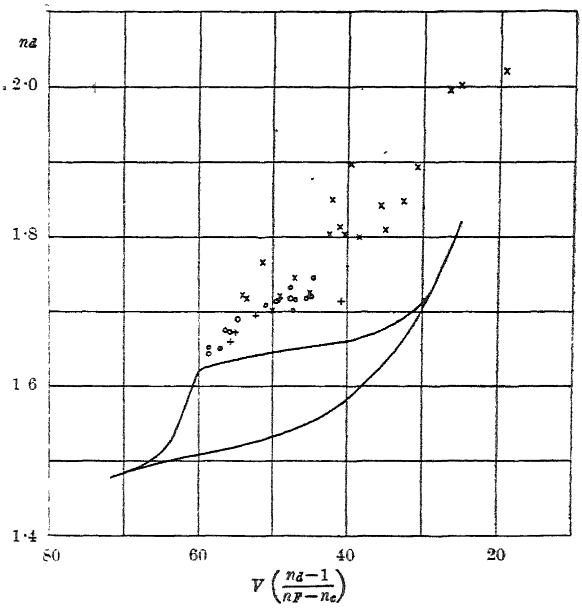
Advances in lens design have led to a demand for new glasses with optical properties different from those available hitherto as outlined in a recent paper by B. K. Johnson[1], who mentions glasses with high refractive index and low dispersion. Non-silicate glasses of this type containing rare earth oxides in high proportions and with optical properties ranging from 1·71 to 1·97 in refractive index and from 54 to 19 in V value have been described in the patent literature[2], but so far as we are aware, only one of them has been made available in Great Britain, namely, one with refractive index $nD = 1{\cdot}745$ and with $V = 45{\cdot}8$.

Examination of the well-known nD–V diagram for optical glasses shows that there is a large field for exploration, and it is desirable that the glass-maker should have some guidance as to the requirements for lenses of various types. On the other hand, without definite information that new glasses are available, the computer does not wish to spend time on designs which utilize optical properties for which there may be no corresponding glasses. It is our hope that this short account of new glasses developed by this Company will be of interest to designers and serve to stimulate experiments in lens design.

The new glasses contain appreciable quantities of silica and boric acid as the network formers, and their exceptional properties depend on the addition of the oxides of barium, lead, zinc and certain other metals. Their optical properties are plotted in the accompanying graph, and they lie between the limits of V value of 60 and 40 and have refractive indexes greater than $(1{\cdot}860 - 0{\cdot}004\,V)$. The American and some new German glasses[3] are included for comparison. The partial dispersions of the new glasses have not yet been determined for all the types, but it is interesting to note that the glass *SBF* 717480 has relative partial dispersions almost identical with those of the standard Telescope Flint 525512[4]. In the diagram, two bold circles indicate the main types on which production is concentrated. Other types not shown may be obtained by interpolation, but it is obviously advantageous to limit the number as there may be developments in another region in the nD–V diagram. The glasses are divided into two general types, those with V values greater than 55, being called Special Barium Crowns (*SBC*) and those with V values less than 55, Special Barium Flints (*SBF*).

The vitreous stability of the glasses, that is, their resistance to devitrification during melting, moulding and annealing, is as good as, or better than, that of the normal types of optical glass, and the compositions and melting technique are such that a high degree of homogeneity can be obtained.

Having regard to their extreme optical properties, the glasses can be considered as substantially free from colour, particularly those with high V value. The transmissions in the near ultra-violet (3650 A.) are generally higher than those for ordinary flints of the same index. Preliminary results indicate that their resistance to weathering is not less than that of normal flint glasses.



The curve encloses the area covered by Chance standard glasses. O, Chance silicate glasses. ×, Kodak glasses, U.S.P. 2150694 and 2206081; and B.P. 462304 and 534680. +, Schott glasses, U.S.P. 2297453.

The method of melting is by electric heating in platinum pots; Faraday seems to have been the first to use platinum crucibles in his classical experiments to produce homogeneous optical glass[5], followed later by Vernon Harcourt, but electricity was not then available to provide accurate control and application of temperature.

Owing to the chemical nature and high cost of the raw materials used, it is not possible to make the glasses on the scale of normal optical glass manufacture, and the process has been limited to small-scale meltings. The manufacture of optical glass on this scale to give freedom from striæ and bubbles has required the development of a new technique such as was not previously possible. The degree of control which can be exercised results in more closely repeatable properties than is possible with large-scale manufacture. While glass of useful size can be obtained on the present scale, the plant is undergoing development to enable larger meltings to be made.

The methods for the development of new glasses are now well established as a result of this work, and we would welcome the views of computers on requirements in optical design.

We have been encouraged to pursue this work by the active interest shown by the Admiralty and the other Service Departments, working through an Interdepartmental Committee under the chairmanship of the Director of Scientific Research, Admiralty.

Mathematics of Biological Assay

If in a biological assay the mean responses, y_{11}, y_{12}, of two groups of n animals to doses of a standard preparation the logarithms of which are x_{11}, x_{12}, are compared with the mean responses, y_{21}, y_{22}, to doses of the preparation under test the logarithms of which are x_{21}, x_{22}, it is often possible to express the relationship between dosage and response adequately by the equations:

$$Y_1 = a + bx, \qquad Y_2 = a + b(x - M), \qquad (1)$$

in which M is a constant difference between log-doses producing equal responses. It is usual to choose pairs of doses having a fixed ratio, so that $(x_{12} - x_{11}) = (x_{22} - x_{21}) = d$. Writing

$$R = \tfrac{1}{2}(y_{22} - y_{21} + y_{12} - y_{11}),$$
$$S = \tfrac{1}{2}(y_{22} + y_{21} - y_{12} - y_{11}),$$
$$\text{and } T = \tfrac{1}{2}(y_{22} - y_{21} - y_{12} + y_{11}),$$

it may be shown that M is estimated by

$$M = \tfrac{1}{2}(x_{22} + x_{21} - x_{12} - x_{11}) - Sd/R, \qquad (2)$$

since R/d is the estimated increase in response per unit increase in log-dose[1]. In a recent communication[2], E. C. Wood has shown that, if a quadratic term is added to the response curves, still keeping the condition that there shall be a constant ratio between equally effective doses, so that

$$Y_1 = a + bx + cx^2, \quad Y_2 = a + b(x - M) + c(x - M)^2, \quad (3)$$

equation (2) still estimates M.

It would be unfortunate if this interesting fact were allowed to conceal the limited applicability of the four-point assay. Equations (1) express the hypothesis that the responses are related to the log-doses by two parallel straight lines, and the data themselves provide a test of the adequacy of this hypothesis. T is a measure of the departure from parallelism of the straight lines connecting the responses to the pairs of doses; if s is the residual standard error in an analysis of variance of the responses by the $4n$ animals (differences corresponding to doses and to litters or any other relevant classification having been eliminated), the standard error of T, as also of R and S, is $s/\sqrt{n}$, and the significance of T may then be judged by a t-test.

Equations (3) express the hypothesis that the responses are related to the log-doses by quadratic curves, still with the condition that the curves are identical save for a constant ratio of potencies; the four parameters, a, b, c and M, may be determined so that equations (3) reproduce the experimental mean responses exactly, leaving no degrees of freedom for assessing the adequacy of the hypothesis. There may sometimes be strong *a priori* reasons for believing that the standard and test preparations have response curves of identical form, in spite of a difference in potency; a quadratic equation such as (3) may then be a sufficiently good approximation, even when a linear is unsatisfactory, and the relative potency is estimated as the antilogarithm of the expression in equation (2). Without this belief, it is unjustifiable to assume the existence of a constant relative potency, and the four-point assay cannot give a valid result unless a low value of T indicates the adequacy of the hypothesis expressed by equations (1). In all cases of uncertainty it is desirable to test at least three doses of both preparations, so that more information on the response curve may be obtained. Without such precautions, a spurious simplicity may appear in the results of an assay, a single figure being said to represent the potency of a test preparation relative to a standard, when, in fact, the relative potency depends on the level of response at which a comparison is made.

The standard error of M, as given by equation (2), is[1]

$$s_M = \pm \frac{sd}{R^2}\sqrt{\frac{R^2 + S^2}{n}}.$$

For any chosen level of probability a value of t may be obtained corresponding to the number of degrees of freedom on which s is based; provided that $g = t^2s^2/nR^2$ is small, the fiducial limits to M are $M \pm ts_M$, but when g is large the precise formula

$$M - \frac{g}{1-g}\frac{Sd}{R} \pm \frac{tsd}{R^2(1-g)}\sqrt{\frac{R^2(1-g) + S^2}{n}}$$

must be used.

Tautomerism of Cyanamide

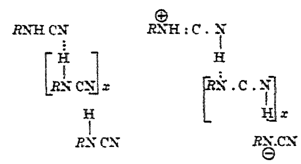
The constitution of cyanamide, since its first synthesis in 1851, has been the subject of a very large number of publications. Whereas the chemical properties of this substance point to the structures NH_2CN and $NH:C:NH$, its physical properties are held[1] to favour the former. The modern tendency is to regard cyanamide as a mixture of these isomers in tautomeric equilibrium[2], with the position of equilibrium considerably in favour of the cyanide structure.

The equilibrium $NH_2CN \rightleftharpoons NH:C:NH$ is a special case of amidine tautomerism, and the tautomeric behaviour of amidines has already been correlated[3] with their associated (hydrogen-bond) structure. Since many of the physical properties of cyanamide are consistent with a high degree of molecular association, it appeared of interest to examine the molecular condition of cyanamide and its N-substituted derivatives to see whether a similar correlation prevailed. A sufficient number of cyanamide derivatives has now been examined to provide overwhelming support for this suggestion, namely, that the tautomerism of cyanamide and its mono-substituted derivatives (RNHCN $\rightleftharpoons$ RN : C : NH) is due to their molecular association.

Molecular weight measurements have been made cryoscopically in benzene solution, or, in cases where the solubility was too low at the freezing point of benzene, in naphthalene. Cyanamide itself was not sufficiently soluble in either solvent to give reliable results, and was measured cryoscopically in nitrobenzene solution. In spite of the donor character of this solvent, and its consequent tendency to simplify the solute molecules, a 2 per cent solution of cyanamide in nitrobenzene showed an association factor of well over 2·0. Molecular weight determinations have been made on more than a dozen N-substituted cyanamides, which are found to fall into two distinct classes: those possessing an unsubstituted hydrogen atom (RNHCN) are markedly associated, their molecular weight rising rapidly with

increasing concentration, whereas those in which there is no free hydrogen (R_2NCN) are substantially unimolecular. It seems clear, then, that the former class owe their associated character no less than their tautomeric behaviour to molecular union through hydrogen bonds (N–H–N), the imino-hydrogen atom of one molecule being shared with the cyano-nitrogen atom of a second.

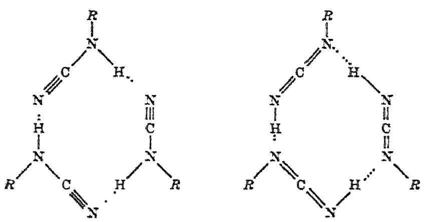
No conclusions can be drawn from the molecular weight evidence as to the type of associated molecules, for the molecular weight – concentration curves show little or no falling off in slope with increasing concentration. This may indicate linear polymers, and regarding the hydrogen bond as a resonance phenomenon[4], a linear polymer of the cyanamide RNHCN containing $x + 2$ molecules is depicted in Fig. 1, in which (a) and (b) are the unperturbed forms of the resonance hybrid.



(a) (b)

FIG. 1.

Cyclic polymers are not excluded, and a practically strainless trimer (Fig. 2) involves no separation of charges in the resonating forms (a) and (b).



(a) (b)

FIG. 2.

Chemical polymerization with formation of substances of the melamine type was, of course, excluded, the cyanamides being recoverable unchanged from the cryoscopic solvent.

Polymers such as those depicted above will possess all the properties attributed previously to the two tautomers RNH.CN and RN : C : NH, but since the polymeric resonance hybrid is neither of these, no separation of tautomers can be expected. Tautomerism owing its origin to resonance polymers of this kind has previously been named *mesohydric tautomerism*[5], and there seems little doubt that cyanamide and its monosubstituted derivatives provide further examples of this phenomenon.

A detailed account of these measurements will be published elsewhere.

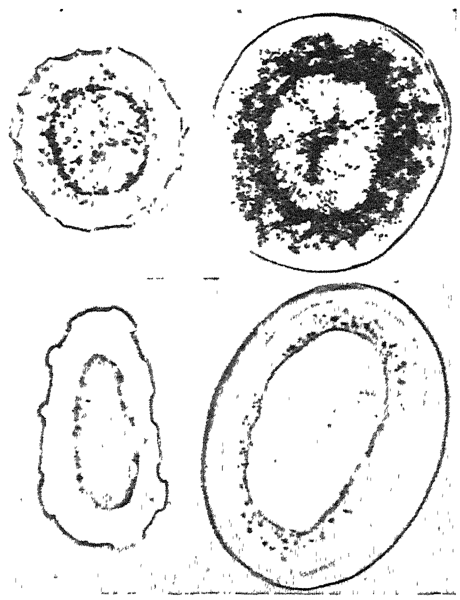
Morphology of Mammalian Hair

DURING a recent histological examination of keratin fibres, transverse sections were made through proximal, medial and distal portions of mammalian guard-hairs. The results obtained support earlier views upon the nature of hair growth[1,2]. Sections through proximal regions clearly demonstrated the alteration in fibre contour which follows upon changes in the hair follicle during the catagen phase. As atrophy of the hair root occurs, corresponding fibre shrinkage gives a characteristic irregular contour to the proximal region of the hair shaft. The accompanying reproduction illustrates the results obtained for guard-hairs from silver fox (*Canis vulpes fulva*) and kolinsky (*Mustela sibirica*).



ABOVE: *C. vulpes fulva*. PROXIMAL REGION (left). ×480. MEDIAL REGION (RIGHT). × 480.
BELOW: *M. sibirica*. PROXIMAL REGION (LEFT). × 650. MEDIAL REGION (RIGHT). × 380.

This variation in fibre contour is accompanied by changes in surface structure. Photomicrographic examination of cuticular-scale structure showed the presence of different scale types in the proximal and medial portions of guard-hairs; for example, kolinsky: proximal region, spinous type; medial region, irregular annular.

A detailed account of the investigation of hairs from members of Carnivora and Rodentia will appear elsewhere.

Gamones from the Sperm of Sea Urchin and Salmon

Hartmann and Schartau[1] have introduced the term 'gamone' to denote substances which are carriers of the interactions between the gametes at the fertilization. Androgamones (A) are those carried by the sperm. Hartmann, Schartau and Wallenfels[2] separated two factors: A I is present in the methanol

extract of the sperm, whereas *A* II is insoluble in methanol. We have carried out some further studies on the androgamones from *Echinocardium cordatum, Psammechinus miliaris, Strongylocentrotus droebachiensis* and *Echinus esculentus.*

The undiluted sperm from the testes was frozen in carbon dioxide snow or in a mixture of this and acetone, and was dried in the frozen state by the 'Cryochem' method of Flosdorf and Mudd[3]. The dried sperm was extracted with methanol. The residue was suspended in sea water and subjected to a temperature of 85–90° for 3–5 minutes. The insoluble part was centrifuged off. A clear liquid was thus obtained. This contains *A* II, which precipitates and agglutinates the jellies. Electrophoresis of the solution after dialysis reveals only one component. The active substance migrates towards the anode at *p*H less than 4·0[4]. The active substance is precipitated by 75 per cent saturated ammonium sulphate.

The *A* II substance is very quickly inactivated by trypsin (in less than 5 minutes at 20° by 0·0025 per cent trypsin Merck). It is evidently a protein-like substance. Its molecular weight is probably less than 10,000[4]. It has even been autoclaved for 30 minutes at 1 kgm./cm.^{2} more than atmospheric pressure without loss of activity. It has a characteristic ultra-violet absorption band at or near 260 mμ. Jelly which has been brought into solution inactivates *A* II. Clupein acts like *A* II, but it is obvious from the electrophoretic data presented above that *A* II is not of histone or protamine nature. The individual amino-acids contained in clupein do not act as precipitating agents on the jellies, nor do a number of other amino-acids tested.

From the sperm of salmon an *A* II fraction is obtained in the same way as that described above. It precipitates the jelly of sea urchin eggs. It has a similar ultra-violet absorption spectrum and is easily inactivated by trypsin, as is the sea urchin *A* II.

The methanol extract was evaporated and the residue was extracted with sea water at 85–90° for 3–5 minutes. A faintly yellow solution resulted. This solution contained *A* I. A drop of sperm was introduced between cover-slip and slide and an equal drop of the extract was added. The *p*H of this was adjusted to about that of sea water. The sperm was immobilized. In other experiments, the dried sperm was extracted directly with warm sea water without previous treatment with methanol (Frank's method[5]). The opalescent extract was as active as *A* II, but no *A* I activity could be demonstrated. It seems doubtful whether fraction *A* I takes any part in Psammechinus or Echinocardium sperm. In undiluted suspensions obtained from the testis, the sperm is very active at the boundary of a drop, where oxygen uptake and outward diffusion of carbon dioxide are sufficient. The *A* I fraction seems in our species to be liberated in sufficient quantities only after extraction with methanol. Nevertheless, *A* I plays an important part in the salmon. The immobilization of the sperm in dense suspension is due to *A* I. On dilution, the sperm becomes mobile, but addition of a solution containing *A* I from the sea urchin or from salmon immobilizes the sperm in a reversible manner. It was found for the salmon *A* I that it diffuses through 'Cellophane'. This is probably true also for sea urchin *A* I. Neither the salmon nor the sea urchin *A* I is inactivated by trypsin.

The methanol extract contains still another factor which may be designated as *A* III. It is active on the surface of the egg. Its presence is demonstrated by the following test[4]. Unfertilized eggs deprived of their jelly are placed in a hypertonic solution (2 ml. sea water + 0·6 ml. 2·5 *N* sodium chloride). When the eggs shrink in this solution, the surface acquires numerous small wrinkles. In the course of about an hour the surface becomes smooth (the duration of the wrinkled state is subject to variations according to the material and the conditions). Unfertilized eggs pretreated for 20–30 minutes with sea water containing *A* III shrink with a smooth surface. In eggs transferred from a hypertonic solution containing *A* III a fairly vivid streaming of the cytoplasm occurs. The action of *A* III may be interpreted as a liquefaction of the cortical layer[6]. *A* III of sea urchin sperm dialyses through 'Cellophane'. It is seemingly not attacked by trypsin. *A* III is not identical with *A* I. The latter factor is more strongly adsorbed by aluminium oxide and hydroxide than is the former. The adsorption experiment was carried out with extract from sea urchin as a front analysis following Tiselius[7]. Only the first portion of the fluid pressed through the aluminium oxide filter is devoid of *A* III. The subsequent portion shows *A* III activity, while no portion shows *A* I activity. Displacement and elution experiments also prove that *A* III is more loosely bound to aluminium oxide or hydroxide than is *A* I.

The solution containing *A* I and III acts as an inhibitor to *A* II, while this latter factor does not impede the action of *A* III.

A I is resistant to treatment with normal hydrochloric acid at 100° for at least 30 minutes. *A* III under these conditions is not destroyed, but its activity somewhat diminishes.

A methanol-soluble factor from both sea urchin and salmon sperm has a tendency to hæmolyse red mammalian corpuscles or at least to change the normal biconcave form of the corpuscles into a spherical form with a smooth surface. These changes resemble those occurring in the sea urchin egg under the action of *A* III. In view of this and other facts, the change of the red corpuscles may be ascribed to *A* III.

Besides the agent which changes the form of the corpuscles, the methanol extract seems also to contain a factor which causes agglutination of the corpuscles.

For a more complete review of literature see refs. 4 and 8. Further details of the results will be published elsewhere.

Blind Seed Disease of Rye-Grass

INVESTIGATIONS on blind seed disease of rye-grass have been continued in Northern Ireland since 1940[1]. In agreement with Neill and Hyde[2,3], and Wilson, Noble and Gray[4], sporodochia producing endogenous microspores have been observed on affected seeds and also in culture.

Inoculation experiments were carried out during the summer of 1941, using the same technique as in 1940. Again *Pullularia pullulans* proved to be non-parasitic. Using the blind seed fungus (*Phialea temulenta* Prill. and Delacr.) and employing suspensions of ascospores and macrospores, heavy infections with the disease were obtained at flowering time with one commercial type and two indigenous strains of perennial rye-grass and one commercial type of Italian rye-grass. When inoculations were made after fertilization, the amount of infection rapidly declined. The seed produced was tested for germination and highly significant negative correlations were obtained between percentage infection and percentage germination for each variety used.

In August 1942 the blind seed fungus was isolated from seeds of sheep's fescue (*Festuca ovina*), bent-grass (*Agrostis canina*), fiorin-grass (*Agrostis palustris*), smooth-stalked meadow-grass (*Poa pratensis*), Yorkshire fog (*Holcus lanatus*) and crested dog's-tail (*Cynosurus cristatus*), by plating out infected kernels on a suitable medium after surface sterilization and bisection[2]. Yorkshire fog and crested dog's-tail were only very lightly infected and the percentage of seeds from which the fungus was isolated was very low. Cultures from bent-grass, sheep's fescue, smooth-stalked meadow-grass together with one from rye-grass were used for inoculation experiments in 1943, and successful results were obtained with meadow fescue (*Festuca elatior*), rough-stalked meadow-grass (*Poa trivialis*) and rye-grass.

Investigations on the control of the disease by seed disinfection were carried out during 1940–43. These included laboratory, pot and field tests. Dry and short-wet treatments with seed disinfectants, including organo-mercury compounds, were not altogether satisfactory. Treatment with hot water for fifteen minutes at 50° C. following pre-immersion for four hours in tepid water, or for thirty minutes at 50° C. without pre-immersion, gave full control of the fungus. There was little, if any, reduction in germination following upon this treatment when the drying of the seed was carried out immediately. These results were confirmed in pot and field experiments, where apothecia were collected from all plots except those sown with seed subjected to the hot-water treatment. It was also observed that, after the hot-water treatment, infected seeds decayed readily in the soil whereas in other cases they remained firm and unchanged.

In a field experiment in 1941, where the plots were separated by paths two yards wide, it was found that no treatment reduced the amount of infection present in the seed produced. This was due to the fact that ascospores were carried from plot to plot to bring about primary infection. In order to overcome this difficulty, small plots, well isolated from rye-grass crops, were sown with infected seed subjected to the hot-water treatment, which was shown by laboratory tests to be completely effective in killing the parasite. Similar plots in other districts were sown with untreated seed. Examination of the seed produced showed that the percentage infection in ten of the plots sown with untreated seed varied from 0 to 38 with a mean of 8; in the case of fifteen plots sown with treated seed the corresponding range was from 0 to 55 with a mean of 11 per cent. These results suggest that infection from a source other than the seed sown had occurred, probably through apothecia produced on infected seed from plants in hedgerows, untopped pastures and waste-ground. Such being the case, seed treatment cannot be expected to provide satisfactory control except under conditions of perfect isolation.

Since 1939 a large number of seed samples have been examined and the results indicate clearly that strains of indigenous perennial rye-grass are more susceptible to blind seed disease than commercial types. The amount of infection has varied from year to year and, since these observations were commenced, serious infection has been recorded only in 1939 and 1943. During the years 1940–42 only occasional samples examined showed heavy infection. In 1941 the seed from one field of indigenous rye-grass, sown with disease-free seed in the spring of 1940, showed infection ranging from 31–55 per cent for six samples examined. In the seed from several other crops, produced from the same parent seed, the disease was absent or present only to a very small extent. On investigating the crop rotations it was discovered that in the former case rye-grass had followed a four-year lea, while all the other crops had been sown on land which had been in arable crops for from three to four years. It seems clear that the amount of infection had been influenced by the previous cropping. Much of the seed produced from these crops was sown in the spring of 1942 and about 160 samples from the resultant crops were examined in 1943. The amount of infection varied and in some cases it was so high as 70 per cent, probably as a result of the suitable weather conditions for infection which prevailed during May and June. A significant result which emerged from this examination was that the seed samples from fields sown with the heavily infected seed did not, on the average, show a higher percentage infection than those from fields sown with practically disease-free seed.

Since rye-grass is of primary importance as a forage crop and as the use of the seed is largely limited to the propagation of the species, too much importance could be placed upon reduced germination due to the incidence of blind seed disease. Until evidence has been produced to show that the causal parasite affects the value of the crop in some other way, it must be assumed that the damage is confined to an attack upon the seed. The seed from indigenous strains is certainly more liable to heavy infection than that from commercial types; but if, on the other hand, the crops from indigenous strains are of much greater feeding value, then a certain reduction in the percentage germination of the seed would appear to be of secondary importance. In Northern Ireland there would be very few, if any, seasons when, by proper blending, the seed could not be brought up to a standard of germination suitable for incorporation in mixtures intended for pasture establishment in non-seed-producing areas. The best seed should be reserved for distribution in seed-producing areas. By this means a supply of seed of the valuable indigenous strains already in existence would be made available until such time as leafy strains resistant to blind seed disease can be introduced.

The occurrence of seasons at irregular intervals when

the germination of rye-grass seed is below average is common knowledge, and all available evidence indicates that this reduced germination is due to the incidence of blind seed disease. The disease must, therefore, be regarded as of long standing, attention having been focused on it in recent years due to the susceptibility to attack shown by indigenous strains of rye-grass.

It is not unlikely that the natural susceptibility of such strains to the disease coupled with their shyness in seed production has operated as a primary factor in bringing about their general elimination from commerce. The continuous harvesting of the seed without sufficient reference to the strain of the grass would operate automatically in the same direction, and the forage value of the crop which, after all, is of the greatest importance, may have suffered in consequence.

White Plumage of Sea-Birds

IT is often considered that the white plumage of gulls, terns, gannets, etc., in temperate climates is in contradiction to the principle of protective and adaptive coloration, and survives only because these birds are relatively safe from attack and able to protect themselves. Thus Cott[1] remarks that "in any normal surroundings" they are "positively conspicuous" but considers that their strength and pugnacity protect them.

As is now well known, aircraft of Coastal Command on anti-submarine patrol are painted white on their undersides. This treatment was devised by Merton of their Operational Research Section on theoretical grounds, to render them less visible to submarines. Since any natural object is less bright than the sky, it will appear dark when seen from below against the sky, though at long distances the contrast will be slight, due to the great amount of scattered air-light between observer and object. Merton showed that a white object will have a smaller contrast against the sky than a darker one, even at ranges of several miles, and that white paint should therefore decrease the range at which the submarine look-outs spotted the aircraft and gave warning to submerge. Surely the same end may have been achieved, by natural selection, in the white coloration of the undersides of many sea-birds which depend for their food on spotting and catching fish very near the surface. If the bird is white its contrast against the sky will be smaller and the fish will be less likely to see it in time to dive beyond the bird's reach. As the visual acuity of fish is much poorer than that of man the ranges involved are short and the reduction of contrast by scattered light negligible; hence the benefit of white coloration will be greater than in the case of aircraft.

The majority of sea-birds (apart from shore-feeders) which have dark plumage, like cormorants and guillemots, are diving birds which swim at considerable depths; it should therefore matter little to them whether fish dive deeper at their approach—perhaps indeed they see fish from below in silhouette, in which case their own dark coloration would be an advantage.

Analysis of Barley from King Tuthankhamen's Tomb

THROUGH the kindness of Mr. J. Philp, chief botanist of the Ministry of Agriculture, Egypt, we recently obtained a small sample of ancient Egyptian barley from the Museum of Antiquities, Cairo, which came originally from the tomb of Tuthankhamen (*c.* 1350 B.C.). The barley is extensively carbonized, but its structure is sensibly undamaged and the germ, for example, with its scutellum and embryo components, is still intact. It has, however, apparently lost a considerable amount of weight and its density is only about two thirds that of fresh English barley.

No vitamin B_1 could be detected in the grain, even in the dissected scutellum. On the other hand, the contents of riboflavin and nicotinic acid, as determined by microbiological assay, were found to be 0·85 μgm. and 28 μgm./gm. respectively: the corresponding values for fresh barley average 2·5 μgm. and 90 μgm./gm.

The total phosphorus in the barley was found to be 414 mgm. per 100 gm. and the phytate phosphorus 0·4 mgm./100 gm. Average values for fresh barley are 370 and 249 mgm./100 gm. respectively. There has, therefore, been practically complete hydrolysis of the phytic acid originally present in the grain, but no trace of an active phytase can now be found. Likewise the grain gives no reaction for phosphatase.

It is surprising to find that a molecule so complex as riboflavin could survive for such a long period. Part of the explanation is to be found in the very low relative humidity in the tomb, while we have also observed that the barley has increased in acidity, a 1 per cent suspension giving a pH value of 4·1 as against 6·25 for fresh barley. We have no information on how the barley was stored: but it is possible that its preservation was helped by an oxygen-free atmosphere created by its own respiration and the oxygen uptake of other products stored with it.

Although the germ was intact, it was found to contain a number of well-defined crystals, and these are being examined by our colleague, Dr. Hinton, in an attempt to establish their chemical identity. It will also be of interest to know if the crystals are composed of a product with a very small velocity of crystallization.

BIOCHEMICAL IMPORTANCE OF INDIVIDUAL AMINO-ACIDS

THE biological importance of a protein is dependent on the extent to which it is able to supply the amino-acids which the animal cannot synthesize for itself. Willcock and Hopkins (1906–7) showed that young mice, fed on a diet in which zein was the sole protein, lost weight and died in about 17 days. The addition of tryptophan to the diet enabled the mice to survive for longer periods, although they continued to lose weight. In 1914, Osborne and Mendel repeated the experiments and found that, in growing rats, the addition of tryptophan enabled the animals to maintain their normal weights, and that with the further addition of lysine normal growth was restored. Tryptophan and lysine were therefore regarded as essential amino-acids, the list of which was afterwards extended to include histidine, threonine, valine, phenylalanine, leucine, *iso*leucine and methionine or possibly cysteine. The discovery of threonine by Rose (1931) was the direct outcome of experiments involving the feeding to rats of synthetic mixtures of all the amino-acids known at that time. The rats failed to grow, and Rose concluded that proteins probably contain an unknown amino-acid, which was afterwards isolated and identified as α-amino-β-hydroxy-*n*-butyric acid (threonine).

Essential amino-acids then, in common with vitamins, cannot be synthesized in the mammalian body and have to be supplied in the diet. Unlike vitamins, which are present in small quantities in the tissues, amino-acids, combined in proteins, form a large part of the total mass of the body, and the quantitative requirements of essential amino-acids are therefore considerably greater than those for vitamins. The deleterious effect of a dietary deficiency of a particular amino-acid will be less marked and sudden, therefore, in the adult animal, due to the great store of amino-acids which the body has in its proteins.

Essential amino-acids may have different biological functions. One may be needed only as a building material for the synthesis of protein, in which case a lack of that amino-acid in the diet will result only in an inhibition of protein synthesis, the severity of the symptoms from which will depend on the quantitative requirements of the body relative to its stores of that amino-acid. Another may be indispensable because of its role as a precursor of, for example, a ductless gland secretion, such as adrenaline, which is probably derived from phenylalanine. Cysteine or methionine are the principal sources of sulphur to the animal body, and are probably precursors of glutathione, taurine, insulin, keratin, etc. Valine deficiency in rats produces characteristic nervous symptoms, involving extreme sensitivity to touch and severe lack of co-ordination of movement, suggesting a special role of this amino-acid in the central nervous system. The precise part played by tryptophan is still a matter of conjecture, but from the severe effects which follow its removal from the diet, it seems evident that it has some special function to perform apart from protein synthesis. Its effect on the growth of one of the simpler invertebrates, Obelia, suggest that it may control the speed of metabolism. Histidine is probably the precursor of histamine, ergothionine, carnosine and anserine (found in goose muscle). Lack of lysine produces no specific symptoms apart from cessation of growth, although animals kept on lysine-deficient diets are not static as regards the development of individual tissues and organs. Thus body, tail and leg bones increase in length, and organs such as eyes and kidneys increase in weight, while others, such as muscle, decrease. Although male genital organs are unaffected, the œstrus-cycle may be suspended. Lysine is thus probably required as a purely passive material for the synthesis of protein.

H. A. Harris, A. Neuberger and F. Sanger (*Biochem. J.*, 37, 508; 1943) have recently shown that lysine deficiency in rats produces cessation of growth and hypoproteinæmia. The number of red cells and the amount of hæmoglobin per unit volume of blood are slightly less than in the controls, and this is interpreted as indicating not so much an anæmia proper as a retarded development of the hæmopoietic system. A comparison of the radiographs of the control and lysine-deficient rats showed great differences in the bodily dimensions. Normals are well covered with subcutaneous fat and muscle as compared to the lysine deficients, in which the degree of calcification in all bones is generally reduced. The epiphyseal cartilage of the long bones is barely visible and histological examination reveals considerable reduction in the number of chondroblasts in the first zone of proliferating cartilage. In the zone of calcified cartilage, the trabeculæ of calcified matrix are heavier in the deficient animals than in the controls. Mitotic figures in the testes are reduced as compared with controls.

The changes observed are assumed to be due to a general inhibition of protein formation, leading to reduced growth of some organs which develop at the expense of others not unlike the picture produced by ordinary starvation. Protein is transferred according to a fixed system of priorities, and the sum total of these changes is constant body weight, although the animal is no longer the same animal. It is noteworthy that lack of one essential building unit in the diet produces essentially the same symptoms as underfeeding, and if only one essential amino-acid is missing from a protein then that protein is rendered unsuitable as the sole source of nitrogen in the diet of the young or adult animal. Cadet de Vaux in Paris during the French Revolution tried to persuade the poor that gelatin soup was a satisfactory and nutritious diet. The poor refused, and their attitude has since been shown to have been amply justified, as gelatin contains no valine, *iso*leucine or tryptophan.

T. F. DIXON.

BRITISH ELECTRICAL AND ALLIED INDUSTRIES RESEARCH ASSOCIATION

THE twenty-second annual report of the British Electrical and Allied Industries Research Association (E.R.A./T341) summarizes the work which has been carried out during the year ended September 30, 1943, and again lists, by titles, the various research reports which have been issued during the year. The work is reviewed under the same eighteen major classifications as last year, among which dielectrics, cables and overhead lines, electric control apparatus, and magnetic materials figure largely.

The report shows that the work of the Association has been carried on during the year by 108 active technical sections, sub-committees and panels formed from workers in industry and academic institutions.

Seventy-five technical reports on various subjects have been issued during the year, as compared with fifty-seven in the previous year.

The Information Bureau has accorded significant help, not only to members but also to Government and Service departments. Many inquiries for translations have been received from members, and these have met with prompt response. The rate of preparation of translations now averages about one a week, and in future a six-monthly list will be distributed to members showing the translations completed during the period. The list will also include bibliographies which have been prepared from time to time in response to particular requests. A complete revision of the annotated list of reports is nearly completed and progress has been made on the complete analytical index to E.R.A. reports. The section on overhead lines will be distributed shortly, and as soon as possible a consolidated index to the complete sections on materials covering all reports to date will be issued. A corresponding issue for technical subjects will follow later.

During the year there has been a further increase in the amount of direct assistance to the war effort given by the Association. The British Coal Utilization Research Association having secured a site near Leatherhead railway station offered part of it to others, as a result of which the E.R.A. decided to negotiate the purchase of an adjacent site and co-operate with the other interested associations in order to secure joint action in matters of common interest and the sharing of common facilities and amenities. It is likely that this will lead to an important group of industrial research laboratories being developed in the area.

Regarding insulating materials, during the year the E.R.A. alone has issued reports representing an expenditure of upwards of £10,000 on the properties of insulating materials. The importance of skilled methods of manufacture, testing and selection has been emphasized under war conditions, and the value of statistical methods of assessment of quality is receiving increasing attention. Now that industry has provided adequate testing facilities for making performance tests on circuit breakers at full power, the study of arcing phenomena and parallel commercial developments are now leading to general development of air-blast circuit breakers for service for which this type is appropriate. A successful application to the High Court by the E.R.A. for extension of the life of its principal patent in this field presented novel features. The special committee established to apply scientific methods to the study of electricity supply technology shows promise of increasing importance, and the willingness of supply engineers to attend committee meetings dealing with important aspects of this matter provides adequate proof of the interest these subjects have aroused.

For many years the Association has sought to secure that attention should be given in Great Britain to the improvement of magnetic sheet steel commensurate with its importance in the design of electrical plant, and during the year all the interests have been brought together and the problem is receiving detailed consideration. The study of surge phenomena constitutes an important section of E.R.A. work. It is interesting to note the work on development of methods of assessing the liabilities of a given overhead line in relation to lightning based on statistical study, and the application of the theory of development of the lightning stroke. Both the requirements of war-time and prospective post-war needs serve to emphasize the importance of the applications of electricity to food production. Having made timely provision for the study of rural electrification problems and all that arises therefrom, the Association continues to conduct and co-ordinate much useful work in this important field.

ENEMY AIRBORNE RADIO EQUIPMENT

At a meeting of the Wireless Section of the Institution of Electrical Engineers held on November 24, C. P. Edwards, of the Royal Aircraft Establishment, South Farnborough, presented a paper entitled "Enemy Airborne Radio Equipment". This paper, to be published in due course in the *Journal* of the Institution, contains descriptions, with more than twenty photographs and diagrams, of the most widely used radio-communication installations and aids to navigation found in German military aircraft, with a brief mention also of Italian and Japanese practice. At the meeting, the author demonstrated a complete reassembly of the general-purpose communication installation used in all German bombers, twin-engined fighters and certain flying boats, this whole equipment weighing approximately 360 lb. This installation includes separate transmitter and receiver units for each of two wave-bands, the medium-frequency covering the range 300–600 kc./sec. and the high-frequency units 3·0–6·0 Mc./sec. The equipment is noteworthy for the fact that the number of types of valves required has been reduced to the minimum: in each of the two transmitters, three valves all of one type are used; while the twenty-five valves used in the two receivers and also in the intercommunication amplifier and miscellaneous valve circuits are all of one type.

An advanced type of rotating-loop direction-finder is incorporated in the installation, with provision for aural reception and visual indication of the direction of the incoming signals. The loop itself is of considerable interest, being of a radically new shape with an iron-powder core, and mounted inside the fuselage under a shallow, protecting stream-lined blister. The loop is turned by the aid of a rotary flexible shaft, and the remote scale is mounted concentric with a repeater compass scale, so that radio bearings may be read off directly, either relative to the aircraft axis for homing purposes, or relative to true or magnetic north and corrected for quadrantal error. An additional receiver with visual indicator is provided for use with the Lorenz system of beam approach towards beacons emitting on frequencies in the region of 30 Mc./sec.

The paper next describes the somewhat simpler radio-telephone installation used in the single-seat fighter, giving one spot frequency in the band 2·5–3·75 Mc./sec. The operational frequency requires to be set up before the aircraft leaves the ground, since no remote tuning control is provided. Production of this equipment probably started in 1935, and it is still in general use. Certain aircraft of the single-engine dive-bomber type are fitted with a remote-controlled medium-frequency homing device in addition to the communication equipment. This comprises a fixed iron-cored receiving loop connected to a receiver covering one frequency band of 250–400 kc./sec.

Other German equipment described and illustrated

in the paper comprises transmitter-receiver units for the frequency range 38·5–42·3 Mc./sec. for air-to-air and short-range air-to-ground telephonic communication, and somewhat similar units as fitted in Army co-operation aircraft and covering the range 42·1–47·9 Mc./sec., with additional facilities for telegraphic signalling.

A brief description is also given of the installation, now known to be obsolete, used in an Italian bomber which was shot down on the east coast of England in 1940. As examples of Japanese practice, brief accounts are given of the equipments used in the "Zero" fighters and certain types of Navy bomber.

The paper concludes with a short commentary on the design and lay-out of the various installations examined, and of the materials and components used. Much of this development and production work is undoubtedly very advanced, and the information which the author has collected and reproduced should prove of value to those responsible for the design and manufacture of radio equipment for aircraft.

RESEARCH AND THE IRON AND STEEL INDUSTRY

SINCE the Heterogeneity of Steel Ingots Research Committee started its work in 1924, this aspect of the interests of the Iron and Steel Institute and the British Iron and Steel Federation has progressed continuously. At present, there are in being some twenty-three such research committees of one kind and another, of which the main, in addition to the Ingots Committee itself, are those concerned with the Alloy Steels (1934), Corrosion (1928), and Steel Castings (1934). A review of their work over a period of twenty years was initially prepared by the late Dr. W. H. Hatfield, and has now been issued*. Hatfield's tragic death has removed the one around whom, more perhaps than any other, these committees and their work have revolved.

The data which have been collected during this time have resulted from the joint efforts of the industry itself, the university, governmental and similar institutions, and affords an outstanding example of the fruitfulness of such an association. The present writer, in the past, has not been uncritical, but this publication provides undoubted evidence of the existence of a far more healthy spirit than obtained until comparatively recently, and, further, one which may be believed to be permanent. The ready willingness of so many industrial research establishments to assist in, and to further, the work being done in academic laboratories, is also deserving of special mention. In any future developments envisaged for the encouragement of research into the particular problems of the iron and steel industry, it is a matter of first-rate importance that this collaboration should be maintained, and that no aspect of research activity should be neglected.

The essential purpose of the present report, to give a fairly detailed summary of the work already accomplished by the various committees, is very well done, and a most substantial addition to our knowledge of the nature of steels, their manufacture and properties, has resulted. How widespread have been the interests of these bodies, especially in more recent years, may be illustrated from some of the researches of the Ingots Committee or its offshoots. These have ranged from studies of slag equilibria to the effect of casting speeds; from the use of radioactive materials in the examination of inclusions, to rimming steels. All these are clearly of fundamental importance from the point of view of the technology of the industry, but many are making a by no means unimportant contribution to scientific knowledge in general. In this connexion, it may be sufficient to cite the work on the accurate measurement of the very high temperatures employed in steel-making.

An interesting aspect of the report is the survey of further work already commenced or contemplated. As, from some points of view, the whole scheme has become more and more interesting as time has gone on, these researches will be looked forward to with keen anticipation. F. C. THOMPSON.

* Iron and Steel Institute. Special Report No. 29: Review of the Work of the Joint Research Committees 1924–1943 of the Iron and Steel Institute and the British Iron and Steel Federation. Pp. viii +176.

TREATMENT OF SHOCK BY HEAT

THE principle of treating traumatic shock by the application of heat has become so well established and has been so much emphasized in first-aid services during the War that the investigations done by A. W. Kay, of the University of Glasgow (*Brit. Med. J.*, 40, Jan. 8), will interest many besides the medical profession.

Mr. Kay has studied the effects of heat on healthy young adults, and he points out that the results cannot be properly applied to patients suffering from traumatic shock; but he thinks that they do suggest that we should study more carefully the effects of heat on shocked people. While the condition known as shock is not yet fully understood, it has been believed, as Mr. Kay points out, that heat helps recovery from shock mainly by relieving the vaso-constriction of the cutaneous blood-vessels and so helping the venous return of the blood. It has only recently been suggested that this vaso-constriction may be a compensatory mechanism and that heat may therefore be harmful.

Mr. Kay's subjects were heated in a hot-air cradle to 38–40° C. for one hour, ten of them receiving normal saline intravenously and five of them receiving plasma intravenously throughout this period. Three experiments had to be abandoned because of the severe symptoms (headache, nausea, exhaustion) and anxiety produced. Nine cases showed evidence of dehydration (dry tongue, weakness and thirst) and all cases showed general perspiration and increased pulse-rate. Nausea occurred in six cases.

The essential factor suggested as the cause of these troubles is general peripheral dilatation, which caused a lowering of the arterial blood pressure and a rise of venous pressure. Since most accepted forms of treatment of shock aim at raising the blood pressure, and since the subjects of these experiments showed a constant and progressive lowering of the blood pressure, the *prolonged* use of heat for the treatment of traumatic shock would appear, in Mr. Hay's opinion, to be contraindicated.

An annotation in the same issue of the *British Medical Journal* gives other references to work on this subject done on man and animals. Further work is clearly required, and it is suggested that intracardiac catheterization might open up a new era in the study of cardiodynamics.

FORTHCOMING EVENTS

*(Meetings marked with an asterisk * are open to the public)*

Saturday, March 4

BRITISH ASSOCIATION OF CHEMISTS (LONDON SECTION) (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Dr. T. J. Drakeley: "Training for the Chemical Industries".

GEOLOGISTS' ASSOCIATION (at the Geological Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Prof. H. H. Read, F.R.S.: "Meditations on Granite", Part 2 (Presidential Address).

Monday, March 6

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Sir William T. Halcrow: "Natural Resources of Great Britain", 3: "Hydro-Electric Power" (Cantor Lectures, 3).

SOCIETY OF CHEMICAL INDUSTRY (LONDON SECTION) (at the Chemical Society, Burlington House, Piccadilly, London, W.1), at 2.30 p.m.—Mr. C. M. Whittaker: "The Applications of Dyestuffs to the Newer Synthetic Fibres".

ROYAL GEOGRAPHICAL SOCIETY (at Kensington Gore, London, S.W.7), at 8 p.m.—Mr. K. de B. Codrington: "Valleys of the Hindu Kush".

Tuesday, March 7

ROYAL ANTHROPOLOGICAL INSTITUTE (at 21 Bedford Square, London, W.C.1), at 1.30 p.m.—Prof. Tadeusz Sulimirski: "Some Remarks concerning the Problem of the Origin of the Slavs".

MANCHESTER LITERARY AND PHILOSOPHICAL SOCIETY (at the University, Manchester), at 5 p.m.—Mr. P. D. Mehta: "Asoka, the Philosopher Emperor".

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5.15 p.m.—Prof. A. R. Todd, F.R.S.: "The Mode of Action of some Vitamins", 1.*

ROYAL PHOTOGRAPHIC SOCIETY (SCIENTIFIC AND TECHNICAL GROUP) (at 16 Princes Gate, South Kensington, London, S.W.7), at 6 p.m.—Mr. H. D. Murray and Dr. G. W. W. Stevens: "Theory and Practice of Reflex Copying".

Wednesday, March 8

ROYAL SOCIETY OF ARTS (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. J. Paley Yorke: "Education To-day and To-morrow", 5: "Technical Education".

PHYSICAL SOCIETY (COLOUR GROUP) (in the Physics Department of the Imperial College, Imperial Institute Road, London, S.W.7), at 2.30 p.m.—Fourth Annual General Meeting; at 2.45 p.m.—Dr. J. H. Saxby: "The Sub-Committee on Colour Deficiency in Industry; a Progress Report".

INSTITUTION OF ELECTRICAL ENGINEERS (TRANSMISSION SECTION) (at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. E. C. Neate and Mr. W. F. Bowling: "Reinforced Concrete Transmission Line Supports".

Thursday, March 9

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 2.30 p.m.—Sir Jack Drummond: "Food Fads and Food Fallacies".*

INSTITUTION OF ELECTRICAL ENGINEERS (INSTALLATIONS SECTION) at Savoy Place, Victoria Embankment, London, W.C.2), at 5.30 p.m.—Mr. Hamlyn Drake: "The Influence of Maintenance Requirements on the Design of Electrical Installation Equipment".

Friday, March 10

ROYAL SOCIETY OF ARTS (INDIA AND BURMA SECTION) (at John Adam Street, Adelphi, London, W.C.2), at 1.45 p.m.—Mr. Maurice S. Collis: "The Achievement of Burma".

PHILOLOGICAL SOCIETY (at the School of Oriental and African Studies, University of London, Malet Street, London, W.C.1), at 4.15 p.m.—Mr. A. S. C. Ross: "A Finnougrian-Indoeuropean Loan-word Problem".

ROYAL ASTRONOMICAL SOCIETY (at Burlington House, Piccadilly, London, W.1), at 4.30 p.m.—Discussion on "Solar Phenomena" (to be opened by Mr. H. W. Newton, Mr. C. W. Allen, Mr. M. A. Ellison and Mr. H. A. Brück).

ROYAL INSTITUTION (at 21 Albemarle Street, London, W.1), at 5 p.m.—Prof. D. M. S. Watson, F.R.S.: "Habit and Evolution".*

UNIVERSITY OF DURHAM PHILOSOPHICAL SOCIETY (in the Physics Lecture Theatre, King's College, Newcastle-upon-Tyne), at 5.15 p.m.—Dr. M. P. Applebey: "The Future of Research".*

APPOINTMENTS VACANT

APPLICATIONS are invited for the following appointments on or before the dates mentioned:

LECTURER IN ELECTROTECHNOLOGY in Santa Maria, Chile—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. D.763.XA) (March 8).

LECTURER (man or woman) IN BOTANY, a DEMONSTRATOR (man or woman) in BOTANY, and a MUSEUM ASSISTANT (man or woman)—The Secretary, Bedford College for Women, Regent's Park, London, N.W.1 (March 8).

ASSISTANT TEACHER (man or woman, temporary) OF MATHEMATICS at the York School of Commerce—The Secretary for Education, Education Offices, York (March 11).

ASSISTANT MASTER (graduate) TO TEACH MATHEMATICS principally, at the Sheffield Junior Technical School for Boys—The Director of Education, Education Office, Leopold Street, Sheffield 1 (March 11).

SENIOR MATHEMATICS MISTRESS at the Middlesbrough High School for Girls—The Director of Education, Education Offices, Middlesbrough (March 11).

LECTURER IN MATHEMATICS AND MECHANICAL ENGINEERING—The Principal, Derby Technical College, Normanton Road, Derby (March 13).

DEPUTY WATER ENGINEER AND MANAGER on the established staff of a large County Borough in Surrey—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. E 887.XA) (March 15).

CHIEF ENGINEER, Port of Basrah, by the Government of Iraq—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Advertising Section, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. E.756.AX) (March 17).

ASSISTANT TO THE REGISTRAR AND SECRETARY—The Registrar, Royal Institute of Chemistry, 30 Russell Square, London, W.C.1 (March 18).

PSYCHIATRIC SOCIAL WORKER (Woman) for Child Guidance Clinic at Harrow—Mr. C. W. Radcliffe, "R.2", Clerk to the Middlesex County Council, Middlesex Guildhall, Westminster, London, S.W. (March 18).

ASSISTANT TECHNICAL OFFICER, ASSISTANT DRAINAGE OFFICERS (2), and an ASSISTANT HORTICULTURAL OFFICER, to the Essex War Agricultural Executive Committee—The Executive Officer, Essex Institute of Agriculture, Writtle, Chelmsford (March 20).

LECTURER IN MECHANICAL ENGINEERING—The Clerk to the Governors, Heanor Mining and Technical School, 30 Mansfield Road, Heanor, Derbyshire (March 22).

METALLURGIST (well-qualified) to take charge of Research and General Laboratories, Heat Treatment, etc., in Sheffield Steel Works—The Ministry of Labour and National Service, Central (Technical and Scientific) Register, Alexandra House, Kingsway, London, W.C.2 (quoting Reference No. F 2048.XA) (March 31).

PROFESSORSHIP OF CHEMICAL TECHNOLOGY—The Vice-Chancellor, University of Madras, Triplicane P.O., Madras India (March 31, by cable; at the same time advise the Office of the High Commissioner for India, General Department, India House, Aldwych, London, W.C.2).

UNIVERSITY LECTURER IN ANTHROPOLOGY—The Secretary of the Appointments Committee, Faculty of Archæology and Anthropology, Museum of Archæology and of Ethnology, Cambridge (April 15).

DRUMMOND PROFESSORSHIP OF POLITICAL ECONOMY—The Registrar, University Registry, Oxford (May 13).

HEADMASTER OF THE PARK HIGH SCHOOL FOR BOYS, and an ASSISTANT MASTER OR MISTRESS (temporary) to teach SCIENCE and MATHEMATICS—The Director of Education, Hamilton Square, Birkenhead.

ASSISTANT TIME STUDY ENGINEER—The Ministry of Labour and National Service, Appointments Office, 2 Calthorpe Road, Five Ways, Birmingham (quoting Reference No. 691).

SCIENTIFIC AND INDUSTRIAL RESEARCH IN GREAT BRITAIN

THE uniformity with which recent reports on scientific and industrial research have insisted that provision for scientific research in Britain was dangerously small before the outbreak of the present War has been taken in some quarters as a disparagement of British achievements. Only the most desultory reading of the reports in question could afford any support for that contention; on the contrary, there is general agreement as to the ability of scientific men in Great Britain and the merits of their achievement, as emphatically as there is agreement that the *per capita* appropriation in Great Britain, both for industrial and for public research, has been far below that in the United States of America and the U.S.S.R. It was a disappointing feature of the report of the Larke Committee on Industry and Research that it provided such meagre information under this head, but there can be no doubt that, had such information been incorporated in that report, it would have corroborated the evidence submitted by the Parliamentary and Scientific Committee.

In a particular field this is well illustrated by the report on methods of building in the United States recently issued by the Ministry of Works. This report of a mission appointed by the Minister of Works in July 1943 shows that the building industry in the United States is considerably ahead of that in Great Britain, not so much in the quality or organization of its research as in the scale on which it is prosecuted, the use made of scientific personnel in the industry and the effectiveness with which the results of research are disseminated. There is no doubt as to the appreciation in the United States of the results of British research and of some features of its organization, such as the Building Research Station. None the less, the main burden of this report is similar to that of all the more important recent general reports: more generous endowment and vigorous prosecution of research, the wider employment of scientific personnel at all stages in industry, and more effective means to secure that the results of research are made known in ways that facilitate their utilization in industry. A further special illustration is to be found in Dr. F. King's recent paper on "Petroleum Refining—A Chemical Industry", read on February 4 before the Society of Chemical Industry, when he powerfully urged the importance of expanding the petroleum refining industry in Great Britain by an adequate research and development policy, so as to provide the basic raw materials for a new chemical industry in the manufacture of solvents, plastics and fibres.

This neglect of new discovery was one of the main reasons for the relative decline in British technical efficiency in the inter-war period, and there is little, if any, dissent from the view that it is essential to remedy this position so that the country may be able to hold its own after the War in the general technical progress. There is now general agree-

ment as to the necessity for a marked expansion in the scope of technical and natural scientific research at the universities and other public institutions, as well as in the facilities for training scientific personnel for such work and for industrial research, and probably also that such expansion should be achieved by a suitable increase of the Parliamentary Votes for that purpose; but there is as yet some uncertainty as to how best research should be stimulated in industry itself.

That is one reason behind the controversy at present proceeding as to the suitability of the patent law system of Great Britain under present conditions and the question of compulsory licensing. The question was raised broadly by Dr. P. Dunsheath in his Atkinson Memorial Lecture and, apart from the suggestion that the present system does not really encourage research and development, the discussion has been linked up, on one hand with the wider question of the control of industry by the State, and on the other with the question of the manner in which the State should encourage research by the remission of taxation. The way in which this question is related to that of obsolescence was well put in an article in *The Round Table*, and superficial discussion may easily tend to blame the patent law system or industry itself for shortcomings which are due primarily to an archaic taxation system, out of harmony with the facts and requirements of modern life. The question whether the State should support, without further regulation, research carried on by private firms, either directly by subsidies or tax remission or indirectly by placing at the disposal of industry the facilities of, or results obtained by, public research institutions, has been examined by Dr. T. Balogh in an article in the *Bulletin of the Institute of Statistics, Oxford*. This illustrates the theoretical character of some of the discussions of this subject from the economic point of view. It may be generally conceded that the State's duty in the encouragement of research and development is primarily to foster self-help, under fair conditions, and not in the main to do the job itself; to favour enterprise of the right kind; and to lend public aid where private effort is insufficient. That the imperative task of research is not to maintain particular industries in a particular state of employment or profits, but to increase the national income, even at the cost of very radical adjustments in the structure of industry and employment, and in the use which is made of the nation's total resources, is much more likely to be challenged from the scientific and technical side of industry.

Dr. Balogh follows Dr. C. G. Paterson in arguing that modern development has changed the whole technical and economic background of the patent law system of Great Britain, and that this has not been explicitly recognized either by a reorganization of scientific research or by patent law. He concludes tentatively against subsidies to private investment in plant of existing types without adequate safeguards. While research into new methods or products may be stimulated in this way, as the new and more efficient methods resulting lead to a potential increase in the national real income and in the international competitive capacity of the country, the danger remains that the effectiveness of the new discovery will be either sterilized or used for the purpose of undue monopoly gains. Measures must, he urges, be taken to safeguard the interests of the community and against retardation of progress.

Dr. Balogh has thus really established the case for reform of the principles of inland revenue, but he goes on to expound the view that, as matters stand in Britain, the State must assume the main burden of increased research, and in the main the expansion of research should be undertaken by the universities or other public institutions. He appears to have in mind particularly the establishment of technical institutions on the lines of the Massachusetts Institute of Technology or of the Continental high schools; but since he suggests that the results of such research should be available on a licence basis to industry, presumably he does not favour a policy of full publication. Stimulus to public and private research in conditions which exclude a misdirection and misuse of the results should, in Dr. Balogh's opinion, be one of the main tasks of reconstruction, but his suggestions are likely to bring him under heavy fire from both the industrial and the scientific sides if they are seriously pressed.

The report on scientific industrial research which has been issued by the London Chamber of Commerce* may well be open to a similar type of criticism, at least as regards its chief new proposal for a central research board, both on the grounds of the practicability of finding the type of personnel necessary, and on the desirability or feasibility of the kind of direct control suggested. Much of the report, it is true, is not new. Reiterating that while the inventive genius and scientific knowledge of Great Britain are second to none, financial policy has put us behind others in the adequate provision of equipment for research, facilities for scientific and technical instruction, and such rewards to successful men of science as would ensure a sufficient supply of men of the first quality, the London Chamber of Commerce concludes that there are three essentials to stimulate research into full and fruitful activity.

Of these three essentials, two are in line with the recommendations of earlier reports, namely, a far greater stream of money flowing into research, and a larger, better trained and better paid personnel. The third, and foremost, is new, namely, centralized and planned direction through a central research board. This proposal has something in common with Lord Samuel's subsequent suggestion at the annual luncheon of the Parliamentary and Scientific Committee that the Lord President of the Council should exercise the functions of Minister of Science in the Cabinet.

Lord Samuel's suggestion is admittedly vague and might not in fact amount to much more than Dr. Dunsheath's proposal for a central co-ordinating secretariat and information service. The London

* Report of the London Chamber of Commerce on Scientific Industrial Research. Pp. 16. (London: 69 Cannon Street, 1944.)

Chamber of Commerce bases its proposal on the view that the support which has been forthcoming both from industry and from the Government for the fundamental type of research carried out by the research associations in Great Britain is insufficient to ensure either in quality or quantity the necessary measure of success. An attempt is made in the report to distinguish between 'fundamental' research and 'pure' research, aimed at the increase of natural knowledge for the sake of increasing knowledge and not for any particular industrial objective. The latter type of research, which in practice is hard to differentiate from long-range research on major technical problems, is regarded as an enterprise which should be financed by the nation, and should be carried on in the universities, though the desirability of close relations between industry and the universities in fundamental research, whether prosecuted in industry or at the universities, is recognized and welcomed.

The main purpose of the London Chamber of Commerce in urging the creation of a central research board to act as a co-ordinating and directing body for all research organizations and to form a link between the Government and the research activities of the country at large is to strengthen the present cohesion of our structure of research. The Advisory Council of the Department of Scientific and Industrial Research is not constituted, nor would its present terms of reference enable it to act, in the way and for the purposes now envisaged. A central research board, for example, should have as a primary function the encouragement of private firms to make available to industry at large, through the board, those discoveries which they did not feel it necessary to retain for their exclusive use. The board should accordingly be empowered to make grants, free of income tax, to private firms for such discoveries as are surrendered to the board, and these payments would be designed to encourage firms to complete lines of investigation which they might otherwise abandon as too remote from the problems of their own industries.

A second function of the proposed central research board would be to ensure that adequate facilities are available in every research association for private work, under conditions which would create confidence, on behalf of small firms. It is also proposed that the board should have the right to intervene and require research associations, in consideration of the public funds placed at their disposal, to undertake fundamental research in directions which it judges to be in the national interest, and to require greater activity on the part of those research associations which, in the opinion of the board, are proving unequal to their responsibilities. It should be the further duty of the board to consider the effect upon trade and industry as a whole of discoveries of a fundamental nature, and to direct the use of those discoveries so that they may be of the maximum advantage to the nation.

The duties of the board would not end here. With regard to the fundamental research carried on in the universities, the board would have the function of ensuring that the results of such research would be applied in the shortest possible time. Scientific men in particular may well begin to wonder what manner of men they may be who will constitute the board, and they will be glad to learn that a highly qualified secretariat is recommended to assist in handling the complex problems involved. Again, it is suggested that the Board of Trade or the Department of Overseas Trade should place before the central research board any facts bearing on the loss of markets by British products, at home or abroad, due to poor quality or high price, and the board should take up the matter with the research associations and with individual firms.

Within its charter a central research board should have the same freedom of action as the British Broadcasting Corporation, under the ægis of, and presumably responsible to, the Lord President of the Council. Five industrialists, with practical experience, four men of science, and three representatives of labour, with a whole-time highly salaried chairman, and the full-time, expert secretariat already mentioned, are suggested as constituting such a board. Alternatively, the Council of the Department of Scientific and Industrial Research might be reconstituted on similar lines and its terms of reference widened to permit it to discharge the functions proposed. The present functions of the Advisory Council for Scientific and Industrial Research might then be discharged by a committee of the board. Finally, the question is raised for consideration whether a central research board should delegate its functions concerned with the universities to the University Grants Committee, or to a separate body concerned with research only, leaving the University Grants Committee to continue to function as at present with regard to all funds not specifically earmarked for research.

With regard to finance, the report considers that the universities should maintain a far larger staff than at present of graduates and of skilled laboratory technicians, and recommends a substantial increase in the number of research fellowships at the universities. The whole of the present annual Treasury grant to the universities would be quite inadequate to enable them to carry on the research which the London Chamber of Commerce regards as essential; indeed it strongly supports the Parliamentary and Scientific Committee in its recommendation that a sum of £10,000,000 should be spent over the first five post-war years in equipping and enlarging the university laboratories, apart from carrying out the expansion of the technical and art colleges on a programme estimated before the War to cost £12,000,000. The report urges, however, that all applications for research grants should come to the proposed central research board and be made by it to the Government, and that similarly all grants made by the Government should pass through its hands.

With regard to the research associations, the report advocates a compulsory levy, where necessary, on each industry for which a research association is thought appropriate. Again, the report is in agreement with the view of the Federation of British

Industries that all expenditure on research and development should be chargeable against revenue, either immediately or over the commercial life of any asset created. It also urges that the cost of pilot plant, as well as of laboratory buildings and equipment, should be chargeable against revenue.

The London Chamber of Commerce is impressed with the need for attracting to a scientific career a larger percentage than at present of men with first-class brains, and urges the up-grading of salaries offered to scientific men in industry, the research associations and the universities. Reference is also made to the importance of technical education and of much more generous endowment of the technical colleges; while finally, the importance of publicity is stressed. Individual undertakings must be made more research conscious, including employers, shareholders and workers alike. The report expresses the belief that there are resources of inventiveness and ingenuity among the people of Great Britain generally which skilful propaganda could assist in tapping.

In the main, the London Chamber of Commerce has merely restated the arguments for the expansion of our research effort on lines urged by the Federation of British Industries, the Parliamentary and Scientific Committee, and other bodies and individuals, with the specific exception of its proposal for a central research board. On this proposal two main comments may be made: first, the organization indicated may prove too rigid and demand too much of the individuals constituting the board, which scarcely seems to fit the machinery of government; and secondly, there is no apparent provision for seeing that research is prosecuted in the biological and social sciences in comparison with the physical sciences to the extent required to maintain a better balance in the advancing front of science. That there is need of some further measure of co-ordination of our research effort is scarcely questioned; but the manner in which that can best be planned or controlled without detriment to the internal discipline or freedom of science is a matter for serious discussion.

Here the report does well to raise the question of the adequacy of the University Grants Committee in regard to research purposes, as was done in the report of the Parliamentary and Scientific Committee. The question is also discussed in a recent memorandum on "The Development of Science" issued by the Association of Scientific Workers, which suggests that to assure adequate financial resources for fundamental scientific research and the wise use of those increased resources, a university council, reporting, for example, to the Lord President of the Council, like the Scientific Advisory Committee, should be formed to extend the functions of the University Grants Committee. It should be competent to discuss in detail all questions of university policy, and, without impairing the independence of the individual universities, it would provide a democratic machinery by which the universities as a whole could take the guidance of their future into their own hands, and the Association suggests that a body of the type indicated in the memorandum should achieve a greatly increased measure of self-government of university science by university men of science.

By and large, the stimulation and endowment of fundamental research on an adequate scale is the first and main problem. Opinion may well be reserved as to how far, or how soon, the creation of a university council of the type suggested is likely to proceed without some external stimulus or some far-reaching university reforms; and if university co-operation has not been particularly marked in the past, the capacity of scientific workers to co-operate even within a limited field of science has not been so successful that the prospect of increased self-government will make any pronounced appeal to them or to the community. The first step may well have to be taken by the Government, following the lead given by some such body as the Parliamentary and Scientific Committee. The adequate endowment and prosecution of industrial research should follow from such steps, once fundamental research has been adequately planned and endowed, and given right relations between the State and industry. The discussions which are already proceeding as to the mechanism of State control, the relations between enterprise and planning, between taxation policy and the encouragement of development and research, and between patent law and industrial research are all to be welcomed as contributing to this end. If such discussions can be kept clear of faction or prejudice, and pressed home to lay bare the fundamental issues, they can do much to indicate the right lines on which the organization of research should proceed in Great Britain. They will suggest conditions likely to stimulate creative thought and invention, and also ensure, not merely that the maximum social use is made of advancing scientific knowledge, but also that adequate effort is concentrated in those fields where social needs, instead of financial or other sectional interests, show it is likely to yield the maximum advantage to the community.

WORK OF IMPERIAL CHEMICAL INDUSTRIES, LTD.

THE record of British industrial achievement during the War remains to be written. A veil of secrecy conceals most of it, and it is only here and there and at rare intervals that a small part of the veil is lifted. Such an occasion was Lord McGowan's speech at the Glasgow Chamber of Commerce recently, when, for the first time during the War, he recorded some of the work of Imperial Chemical Industries, Ltd., emphasizing the fact that it was only a small part of the company's activities of which he could speak. The system of private enterprise on which he said Britain's national greatness had so largely been built had been criticized and misrepresented, and it was the duty of British industry to answer vague innuendo with definite fact and record of real achievement. Especially was it a duty owed to the workers and management class who, so far as

his own companies were concerned, had worked faithfully through more than four years of strain and stress, to deliver the goods both to the fighters in the field and to the people at home.

Though designedly limited in scope, the record was impressive, an outstanding feature being the company's pioneer work in the production of oil from coal, a triumph of courage, foresight, research and engineering skill, none of which, said Lord McGowan, would have been forthcoming in adequate degree unless private enterprise had been free to run the risks involved. No State department could have taken such a decision, involving expenditure of millions sterling; and if it had, Parliament would have vetoed the project. As a matter of fact, the decision to erect a plant at a cost of £3,000,000 was carried in the face of strong opposition in Parliament and in the Press. Lord McGowan said:

"I.C.I. were then accused of gambling with shareholders' money and wasting money and energy by making something which could be brought from overseas much more cheaply. What has happened? Before the War that plant gave much new employment at a time when unemployment was rife. It used British coal to make motor spirit instead of this being imported. Its operation afforded technical experience which was very valuable when applied to other products. From the national aspect it was vital."

All this and much else has been more than confirmed during the War. I.C.I. and companies like it have, moreover, formed the only source from which men with experience of large-scale operations could be drawn as key men to operate the vast ministries established for war purposes. In numerous other fields besides the manufacture of oil from coal, I.C.I. has done invaluable work, most of which is based mainly on peace-time research carried out by the company.

Lord McGowan said that he had been astonished by the amount of research and invention since 1939, but most of the results must remain secret for obvious reasons. There is at all events conclusive evidence that the British race has not lost its spirit of inventiveness, and all enemy devices have been more than matched on sea or land or in the air. His company had many inventions which would prove invaluable in peace as in war, such, for example, as synthetic fibres and new kinds of plastics, to say nothing of the many fruits of agricultural research. They were already planning a vast post-war programme which would, among other things, contribute substantially to the provision of full employment envisaged by the Government, and involve an expenditure of many millions of pounds over the next five years for plant replacement, extensions and new factories, including many required for new products. Lord McGowan emphasized that private enterprise is quite capable of showing that spirit of adventure and courage on which the British Empire has been built. His own company, he said, is not peculiar in this: throughout the whole realm of British industry the same spirit reigns, and only asks for freedom and scope to exercise itself.

The student of political and social science should have much on which to ponder here, though it is difficult in such a case to disentangle political bias from scientific objectivity. The address has been criticized as a record that does not necessarily support the doctrine of private enterprise and as not presenting a correct picture of the financial support given, and risks incurred, by the State, for example, in the oil-from-coal enterprise. As a scientific journal we cannot take sides on the political issue; nevertheless, the extent to which scientific research on a large scale has justified itself in this particular example of private enterprise is very impressive. Further, it will be agreed that there appears to be in British industry abundant evidence that the love of adventure and enterprise for its own sake is often as powerful a motive as profit-gaining. It is sometimes complained that we can have no science of society or of politics in the strict sense because we cannot have the same exactness of controlled experiment as in chemistry and physics. One is a little weary of this very unhelpful comparison. At all events the student of political science, if we admit the validity of such, can approach these problems in a scientific spirit, collect such experimental data as are available—frequently more abundant than is commonly supposed—and weigh and evaluate motives and causes with an open mind unclouded by political prejudice.

APPLIED CHEMISTRY

Thorpe's Dictionary of Applied Chemistry
By the late Prof. Jocelyn Field Thorpe and Dr. M. A. Whiteley. Fourth edition, revised and enlarged.
Vol. 5: Feh–Glass. Pp. xxiv+610. 70*s.* net.
An Abridged Index to Volumes 1–5 of the New edition of Thorpe's Dictionary of Applied Chemistry. Pp. 20. 3*s.* net.
Vol. 6: Glau.–Inv.; with an Index to Vols. 1–6, by Dr. J. N. Goldsmith. Pp. xii+611. 80*s.* net.
(London, New York and Toronto: Longmans, Green and Co., Ltd., 1941, 1943.)

THE troubles of producing such a work as this are manifold even in peace-time. When to war conditions we have to add the death of one of the editors, Sir Jocelyn Thorpe, it is really surprising to see that the standard of contributions in these volumes reaches such a high level. Dr. M. A. Whiteley in a foreword refers to the abridged index to Volumes 1–5 published at the same time as Volume 5, and indicates by the phrase "had the Dictionary been published as a complete work" that perhaps no more volumes might appear during the War. Since then, an editorial board has been formed comprising Prof. I. M. Heilbron, Dr. H. J. Emeléus, Prof. H. W. Melville and Prof. A. R. Todd. Dr. Whiteley continues as editor and Dr. A. J. E. Welch as assistant editor. It is hoped to complete the current edition with eight further volumes, published at yearly intervals, and Volume 6 is the first of the new series under the editorial board.

It might be thought that the board of editors are better constituted to produce a dictionary of pure chemistry than one dealing with the applied side. This idea is rather emphasized by the articles on heterogeneous reactions and homogeneous catalysis

which are mentioned on the fly-leaf to Volume 6 as being innovations in the new series to give greater emphasis to physical chemistry. These articles are definitely more suitable for a text-book on pure physical chemistry. An applied chemist will find that a reasonable appreciation of the fundamentals of aerodynamics together with diffusion theory will be far more helpful in actual practice than the theoretical material given under the heading of heterogeneous reactions. Hydrogen ion concentration has very many and varied applications in industry, and books have been written on the subject. Here, however, it is dismissed in a short notice on how it can be measured.

This lack of attention to the word "Applied" on the title-page is shown in other ways. Practically no attention is given to the economic side of chemical manufacture. As an example, the article on glucinium might be taken. If anyone wished to manufacture beryllium at the present moment, he would be ill advised to think that the information given him in Volume 6 of this dictionary is sufficient for his purpose.

It is invariably advisable when adopting an applied process to make a thorough search of the patent literature. It would therefore be more comparable with commercial conditions if the patent references outnumbered the others. Actually, the reverse is the case.

There would seem to be a requirement for a simple statement to act as a guiding principle in applied chemistry. The physicist has, for example, Fermat's principle, which states that, "The path of a ray of light from point to point is always such that the time taken by the light to traverse it is a minimum". Similarly, in the realm of mathematics, we have the names of Maupertuis and Hamilton and the Principle of Least Action. In applied chemistry the principle could be stated as, "The production of one chemical compound from another will follow such intermediate stages as result in the time taken to make a unit quantity of the product being reduced to a minimum".

This statement might sound like a platitude, but experience goes to show that its importance is only very slightly understood even in circles where the level of intelligence on other matters is very high. The phrase 'time taken' requires perhaps further definition. The time taken in manufacturing the plant for carrying out the reaction, the time taken in producing the energy supplied to the reaction in the form of electricity, steam, etc., and the time which is covered by the various items of chemical works costing are all best expressed by a monetary value which allows the time factor to be expressed in comparable units. The expression 'man-hours' is possibly the more justifiable unit but is not necessarily so easy to compute.

The outstanding feature of Volume 5 is the collection of articles on fibres. They include "Cotton" by Dr. A. J. Turner, "Rayon" by J. M. Preston, "Finishing Textile Fabrics" by E. Clayton, "Animal Wool" by Dr. J. B. Speakman, "Vegetable Fibres" by E. L. Hill, and "Silk" by Dr. C. S. Whewell. These articles also raise a point of interest to the general reader seeking information. Would it not have been better to have preceded this collection of articles by a short introduction on the industry as a whole and the meaning of the numerous technical terms used in it? Nearly all the ancient industries such as textiles, leather, brewing, etc., have a wealth of technical words which do not appear in the usual dictionaries and which therefore need defining for the non-expert. Thus under "wool", we read about wool quality as estimated by the grower and referred to as "60's–64's Cape Merino wool", but how does the grower estimate the wool, and why does he use these numbers? What is meant by "denier" and "counts"? How does the length and thickness of the fibre affect the subsequent processing? Perhaps a Baer diagram might help the novice. What are the principles which affect the wearing properties of the textiles? Why are some cold and some warm to wear? Why do some crease and some drape? It might be argued that these are not chemical problems, but they are at least the qualities which ultimately influence the direction of the policy of future development of all chemically produced fibres. Attention should also be directed to an extensive article on glass by Dr. H. Moore, others on fuel by Dr. G. W. Himus, and on coal and water gas by Dr. H. Hollings and E. G. Stewart and W. A. Voss respectively. Under fermentation, the late Sir Arthur Harden writes on the alcoholic side, Dr. J. H. Birkinshaw on mould and Dr. M. Stephenson on bacterial. Other articles worthy of mention are on fertilizers, by Dr. B. Dyer, formaldehyde, by Dr. H. M. Stanley, and fluorine, by Dr. H. J. Emeléus.

Volume 6 also contains a number of interesting articles, especially those by Dr. E. H. Rodd on indigo dyestuffs, Drs. E. Lewkowitsch and H. E. Cox on glycerine, H. S. Coles and Dr. P. H. Sykes on hydrogenation, Sir T. K. Rose on gold, W. H. Hoffert on gum inhibitors, Dr. D. Burton on glue, Prof. G. A. R. Kon on hormones, Dr. C. A. Mitchell on ink, Drs. J. A. Kitchener and M. Carlton on hydrogen peroxide, Dr. R. Holyroyd on coal hydrogenation, and Dr. A. J. E. Welch on helium. The article on grassland by Dr. J. A. Hanley might well have been expanded in view of the importance of its proper utilization and of the drying of grass for storage in relation to the agricultural economy and self-sufficiency of the nation. Similar comments might be made of A. G. Pollard's articles on gooseberry, grape, grapefruit, honey and huckleberry, even after allowing for the nostalgic feelings they engender after these years of war.

M. B. DONALD.

NEW LIGHT ON TELEPATHIC PHENOMENA

Experiments in Precognitive Telepathy
By S. G. Soal and K. M. Goldney. (*Proceedings of the Society for Psychical Research.* Part 162, December 1943.)

THE experiments here described, which were conducted by the authors during about two and a quarter years, are some of the most interesting and suggestive hitherto recorded. For a number of years the Society for Psychical Research has been supporting a number of experiments in the field of what has been called 'extra-sensory perception', and gradually a mass of evidence has been accumulated which is throwing a good deal of light upon phenomena which have been perhaps some of the most hotly disputed in the whole field of recent work in psychical research.

Generally speaking, the essential core of the experiments consists in the examination of the scores

attained by 'guessing' symbols or pictures in sets of five cards for convenience of statistical analysis. In a number of these tests the subject tries to guess the symbol or picture on a card that is being looked at by an experimenter seated in an adjoining room, his score being later examined to ascertain if he had attained more correct hits than the theory of probability would predict.

Now since the experiments were first started, there has been a very large volume of criticism designed to expose alleged sources of error in the actual work and faulty employment of statistical theory in evaluating the results. In the present series it would seem, judging from the record presented, that such criticisms would be beside the point. Rarely has such scrupulous care been exercised to avoid all possible source of error, and the statistical methods employed were so simple that attempts to discredit them would probably be a waste of time. Moreover, some of the results obtained excluded by their very nature many of the commonly alleged sources of error, and at the same time revealed some surprising effects which had been suspected and later proved to have occurred in previous experiments.

In the past, the prevailing tendency was to study the success obtained by the percipient in guessing the symbol which was being contemporaneously looked at by the agent. In a number of such cases it seemed that certain subjects were successful in scoring over a considerable period many more correct hits than the theory of probability would lead us to expect. But at the same time it appeared that when the records were carefully examined, the 'successes' were not always of the 'now or never' type, but a kind of displacement occurred both backwards and forwards; so that it seemed that at times the card images were becoming known to the percipient before the agent himself was consciously aware of them.

In the present series of tests this phenomenon is further examined, since the subject with whom the work was done appeared to find it easier to score hits, not on the card that was being looked at by the agent, but on the cards which immediately precede or follow it in sequence. The normal rate of guessing varied between limits of 50 sec. and 80 sec. for twenty-five calls, but when this rate was speeded up the cognition of the card in advance of that being looked at by the agent was replaced by a cognition of the card *two ahead* of the one being concentrated upon. This very remarkable effect is in itself sufficiently surprising, while at the same time it disposes of much of the criticism which might have been valid in badly conducted experiments where scores were solely confined to the card being looked at by the agent.

The theory that these effects are due to chance coincidence is considered by the authors of the reports to be completely untenable. For example, to take the one-ahead or precognitive (+1) guessing only, the results are highly significant, for the excess is equivalent to 13·6 standard deviations with odds of more than 10^{35} to 1 against chance.

In discussing the interpretation of these phenomena the authors very wisely make no attempt to deal in any way fully with their psychological and philosophical implications. It is clear, however, that if the results be upheld, light may be thrown not only upon our ideas of time but also of the nature of memory; and moreover, it seems that the earlier and naïve ideas of 'thought-transmission' may have to be abandoned. In any event we have here another step forward in the design of experiments of this kind, and the authors are to be congratulated upon their arduous labour, their scrupulous care in conducting and recording their work and their wisdom in not attempting facile explanations to describe the nature of phenomena the meaning and interpretation of which are likely to elude us for a long time to come.

EARLY SPANISH POSSESSIONS OF THE NEW WORLD AND FAR EAST

Compendium and Description of the West Indies
By Antonio Vázquez de Espinosa. Translated by Charles Upson Clark. (Smithsonian Miscellaneous Collections, Volume 102, Pub. 3646.) Pp. xii+862. (Washington: Smithsonian Institution, 1942.)

If one has a complaint against the editor and the producers of this important work, it is that the title is seriously misleading. Mr. C. U. Clark has provided a most informative introduction, and there is a very full index. The main body of the text, running to nearly 800 pages, is a translation of a manuscript in the Vatican. The original, written by Antonio Vázquez de Espinosa, for the Council of the Indies, was called a description of the Indies and dealt with all the Spanish territory in the New World as well as that in the Far East. We have here, therefore, a detailed account of a large part of North, Central and South America, the Philippines and Moluccas as well as what are now known as the West Indies, as it was about the year 1620.

It is impossible in a short review to do more than allude to the many interesting features of this work, only a small part of which has been previously published. There are valuable details of discovery, with a new account of the notorious Aguirre. Natural phenomena, like earthquakes and floods, trees, cultivated plants, mineral resources, the customs of the native population, and full details of the Spanish colonial administration fill the pages of Espinosa's work. He was a Carmelite missionary and was therefore naturally interested in church matters: and education figures largely. But there is no undue praise of what the Spaniards had accomplished. His descriptions of depopulation, "a general curse in the Indies", neither conceal the facts nor avoid the inevitable consequences, though not all were attributed to misconduct or bad administration. On the other side of the account are the constructive works of the Europeans. The great city of Lima, for example, known as The Kings, founded in 1533, is minutely described, with its irrigation works, its water supply, its rectangular blocks of buildings separated by wide streets, its four plazas, its government buildings, churches, ecclesiastical dignitaries, convents, nunneries, hospitals, university, colleges, and, two leagues away, across an arid plain, the port of Callao with its garrison, shops, stores, mills, and a good, safe harbour "free from shipworms", for "the sea water is so cold here that they chill beverages in it".

Such descriptions, with immense detail of great interest, are frequent. In short, this work will provide historians and naturalists with invaluable information on all parts of the old Spanish colonial world.

J. N. L. BAKER.

ORIGIN AND ACTION OF DRUGS

By HENRY McILWAIN

Leverhulme Research Fellow, Department of Bacterial Chemistry (Medical Research Council), The University, Sheffield

DETAILED study of the action of drugs constitutes pharmacology, but it is doubtful whether study of their origin has reached the level of a scientific subject, though it is described by materia medica or pharmacognosy, and incidentally by biology and chemistry. It is the object of the present survey of therapeutically active substances to show that both their actions and, of naturally occurring drugs, their origins, have additional significance when considered together as aspects of comparative biochemistry.

Attempts to find theoretical connexions between the sources and the properties of drugs have been made many times during the past five hundred years. The subject greatly interested the early naturalists and carried to their work the practical stimulus of possible application in medicine. In pre-scientific times, writers of the early herbals (for example, the German Herbarius[1] of 1485) saw in the fact that mineral and plant products affected animals an indication of a common divine origin of all Nature and expressed the mode of interaction through the four elements; but their outlook had not the objectivity necessary to a scientific study. Among working hypotheses it appears to have supported mainly astrological beliefs and the doctrine of signatures[1,2] which were of value to medicine only in so far as they led to investigation of the virtues of plants.

Certain more objective connexions between the medicinal properties of some plants and their own structural characters have been incorporated in various botanical classifications, and many are still recognized as valid. They are of more significance to our present study, though they offer only a partial solution to it. When medical aspects of botany constituted a major part of the subject, classification of plants was frequently on the basis of their medicinal properties. Other affinities between plants were, however, obvious, and some of these—the petal arrangements of crucifers, or the type of inflorescence of the Compositæ—formed the beginning of natural classifications. There was a significant intermediate period when, in the same volume, some plants were grouped according to structure and others according to their use—a period when botany was beginning to develop as a subject in itself, but was maintaining a close relation to medicine. As the natural classification of plants evolved, the part played by medicinal virtues as differentiating characters declined, though even in Linnæus's rigid system it was evident that a certain connexion existed between morphological and medicinal properties. This was, understandably, emphasized by Linnæus and his protagonists[2,3,4] as being a valuable outcome of the study of taxonomy. The later, more fully developed, natural classifications could claim even closer connexions with the properties of plants, and these were expressed by A. L. de Jussieu and especially by A. P. de Candolle[4]. De Candolle was, indeed, able to use therapeutic properties as differentiating characters in a few debated instances in taxonomy. It is interesting to us now to note that this aspect of comparative biochemistry was contemporary in origin with the present biological classifications.

As biology and chemistry grew as subjects in themselves, such connexions tended to be forgotten and it was considered surprising that a morphologically based classification should receive support from the comparative biochemist[5]. This was especially so at the end of the last century, when many botanists and chemists referred to alkaloids as waste products: they were neither fish, flesh nor fowl to the fat, carbohydrate and protein biochemistry of the day. Since then, ecological studies have tempered such opinions; and alkaloids, glycosides and other substances of pharmacological action have been more generally credited with defensive or offensive powers of value to the organisms producing them. This aspect had indeed never been entirely lost, but higher plants and animals are now realized as being far from alone in producing materials deterrent to the growth or predation of other organisms. Recent studies of mutually antagonistic relations between micro-organisms have added further examples both to this very general phenomenon and to practical therapeutics. But what is the basis for this mutual interaction? When such processes exist, they may be of value to the organisms producing the inhibitory material, but not all such interactions can be regarded in this way. Often the materials are produced only under peculiar conditions of growth, or are highly active against organisms with which they do not normally appear to come into contact. That this is so may indicate only our ignorance of details of their past or normal existence, but many minor interactions take place between organisms not usually credited as antagonistic; and such interactions can be in the direction of either antibiosis or symbiosis according to environmental conditions. Are we then to regard the interacting materials as chance metabolic products—an elaboration of the suggestion of alkaloids being waste products[6]? If so, why should the interaction of product and organism be so universal? There are general similarities between fundamental processes in most living organisms; but what basis do these give for expecting antagonistic relationships?

Let us approach the problem by returning to an earlier point. The possible protective value of a compound to an organism provides a basis for natural selection of the organism producing it, but not for the origin of the compound. Sometimes, inhibitory compounds bear resemblances to other naturally occurring compounds of known biochemical importance; at other times, a given compound itself has either stimulating or inhibiting properties under different circumstances—in different organisms, or in different concentrations[7]. It is upon the basis of such relationships to metabolic processes, both in the organism of their origin and in that upon which they act, that the present account will consider the origin and action of biologically active substances, including those which have found application as drugs.

A General Basis for Pharmacological Action

Drugs are, or owe their activity to, chemical substances; the preparation of the virtues of plants in defined form, amenable to exact study, was a major result of early applications of chemical methods to pharmacology. The late nineteenth century application of physics and chemistry to the study of the action of drugs was not so secure; the peculiar characters of drugs are exhibited primarily towards living organisms, and the correlations suspected between these characters and the physical and

chemical properties of the agents exist but are relatively limited in extent. Their discovery seemed an immense progress, and its contribution to the impression that drug action was one of material interaction with living cells was an important one; but such correlations left untouched the major problem of how a minute quantity of a *substance* could affect a living *process*. The solution of this problem required a further analysis of living processes. Thus, early workers in chemotherapy and pharmacology attempted to consider the actions of drugs in terms of their affecting the known vital processes of nutrition and respiration[8]. This left the mechanism of the required connexion entirely hypothetical; a closer analysis was required to find the systems, peculiar to living organisms, which were affected by drugs and were of types as varied as the receptors of pharmacology would suggest.

Such analysis has proceeded indirectly and is connected with our present subject through the following steps. (*a*) The classical drugs represent only one type of chemical substance capable of specific interaction with living systems. It is a major characteristic of other reactions between substances and processes in living organisms that they commonly occur through, or under the control of, enzyme systems. In intermediary metabolism, the necessity for magnesium salts in fermentations, for flavine nucleotides in amino-acid oxidation, for iron-porphyrin compounds in reactions with hydrogen peroxide, have been found due to these substances forming parts of specific enzyme systems. (*b*) Following upon the recognition of the importance of enzymes in living processes, certain pharmacological agents were demonstrated to owe their specific effects to actions upon enzyme systems (see below). (*c*) Many substances of critical importance in intermediary metabolism are of widespread natural occurrence and can function in organisms other than those in which they originated; and both in the organism of their origin and in those in which they secondarily act, they are connected with enzyme systems. This is true not only of the general categories of carbohydrate, fat and protein but also of substances more akin to classical drugs in their potency and specificity of action. Thus aneurin functions in pyruvate metabolism both in the yeasts and bacteria which synthesize it and in the animals to which it is a vitamin; similar details can be given of nicotinamide and riboflavine derivatives.

The following paragraphs present evidence for a basically similar, though more complex, state of affairs with respect to pharmacological agents in general. The first two points relate to the natural occurrence of biologically active substances, and the latter two to the behaviour of such substances in biochemical systems.

(1) *The quantities of such substances produced by different organisms, or occurring in different parts of them, are very variable.* It is not surprising, or important in the present connexion, that this should be true of carbohydrate or fat; the significance arises in the variable occurrence of substances of more specific action. This is especially well documented with respect to vitamins. Compilations[9] of the vitamin contents of foodstuffs (mainly organs or tissues of higher plants and animals) show variations of many hundredfold and frequently to 10,000-fold in their contents of vitamins A, B_1, B_2, C and of substances of vitamin D activity. This assessing discounts materials described as possessing only 'traces' or 'none' of the vitamins, and does not include values for prepared materials such as bread or oils; the range is thus minimal. Relatively few micro-organisms have been examined in this way, but considerable variations in vitamin production between only six species of bacteria are reported by Williams[10]. Yeast strains can vary considerably in their production of such substances[11].

(2) *In different species, a given function may be performed by related, and not identical, substances or processes.* A classical example is the different forms of excretion of nitrogen in mammals, birds and teleosts, when physiological reasons for the differences can be suggested[5]. They are necessarily associated with differences in the enzymic make-up of the tissues of the different animals, notably with variations in the occurrence of arginase. Again, creatine phosphate in the muscles of vertebrates is replaced by arginine phosphate in the invertebrates. The varying pyrrole respiratory pigments of vertebrates, molluscs, and annelids afford further examples. Among processes, interesting differences exist in the enzymes oxidizing glutamic acid in animal tissues and in yeast, which require respectively coenzymes I and II[12]. Detoxication of benzoic acid can be by glycine or ornithine, and of phenylacetic acid by glycine or glutamine, in different—often closely related—species[13].

(3) *A substance normally essential to a particular process may, by being present in excess or under different conditions, inhibit the process.* Examples of the inhibition of enzyme reactions by excess substrate or products are common[14], and have been given as a basis for many of the following processes of whole organisms. In microbiology: 10^{-7} *M* nicotinic acid is necessary for growth of dysentery bacilli, but higher concentrations inhibit it[15]; small quantities of *p*-aminobenzoic acid, preformed or synthesized by the organism concerned, appear necessary to many micro-organisms which are inhibited by higher concentrations[16]. A given amino-acid (threonine, valine, leucine) may promote or inhibit growth of *Bact. anthracis* or a Neurospora strain according to the nature and quantities of other amino-acids present at the same time[17]; in these cases the balance between stimulation and inhibition is extremely delicate, and small structural changes or concentration differences have very large effects. The phenomenon is also found in growth of *Proteus morgani*[18]. Rats are injured by diets of high tyrosine content[19], though the substance is a constituent of their proteins. Ill effects following excessive vitamin intake may also be quoted; hypervitaminosis-D (and probably -A) have been reported, the latter instance[20] being of especial interest as it was observed in man and rats following ingestion of natural foodstuffs and not of a concentrate.

(4) *The processes associated with a given substance may be inhibited also by substances structurally related to it.* Again, this is well-documented in enzyme reactions[14], succinic dehydrogenation being inhibited by malonate; dehydrogenation of lactate, by other α-hydroxyacids; hydrolysis of fats, by alcohols and phenols, and of peptides, by other amino-acids. Transamination between keto-acids and amino-acids is inhibited by certain fatty acids[21]. The phenomenon also occurs in growth of micro-organisms[7,8,22], when the growth-promoting effect of nicotinic acid may be prevented by pyridine-3-sulphonic acid; of aliphatic aminocarboxylic acids, by aminosulphonic acids; and of pantothenate, by pantoyltaurine and by a number of other analogues. Inhibition by indole-

acrylate is annulled by tryptophan; that by ethionine, by methionine. Such effects may also be reproduced in higher organisms[23] by analogues of vitamin B_1, of vitamin C, and of the anti-hæmorrhagic K vitamins. Actions in many of the more complex systems have again been referred to enzymology.

Biological Interactions in Relation to Pharmacology

The apposition of paragraphs (1) and (2) with (3) and (4) leads to the following conclusion: that known properties of enzyme systems, and the observed variations in the occurrence and structures of metabolically functioning substances of living organisms, provide a basis for processes in one organism being affected by products from another. This does not exclude other bases for such actions; but is sufficient to suggest pharmacological action to be inevitable. If, however, the above factors were the only ones to be considered, such action would not be expect d to be associated with many characters which are, in fact, observed. Detoxication mechanisms in animals and the association of substances of pharmacological effects with special structures (in nettles or snakes) emphasize that biological interactions have not been taken into account. Pharmacology is concerned with aspects of the behaviour of animals which have evolved while dependent upon other organisms for food, and of plants to some extent dependent upon animals for fertilization and dissemination. All can persist only in so far as they maintain their own characters in spite of, or through, their relations to other organisms and to their environment in general. The connexions, discussed earlier, between the position of some organisms in natural classification and in content of pharmacologically active agents presumably persist because such agents are of value to the organisms producing them.

Two types of behaviour can be recognized as developed from the simple, inevitable type of interaction to be expected from paragraphs (1) to (4). First, both animals and plants elaborate agents which are much more potent in their damaging or obnoxious properties than are, for example, vitamins. Secondly, animals react to a large number of deleterious substances by not assimilating or by rapidly excreting them; and by changing them to non-toxic substances by combination or breakdown. Many of the detrimental interactions with potential drugs are thus normally avoided by the various means by which organisms are found to maintain their independence, but the procedures of isolation and administration of drugs are ones which would be expected to break down such independence. A particular tissue, organ, or substance is commonly selected and put to intimate contact with a wound, the eye, alimentary tract, or bloodstream of the animal receiving the drug. Micro-organisms, during their growth in common media, are in particularly intimate contact and are found to exhibit mutual interaction to a high degree, both in the sense of symbiosis (for example, through the production by one organism of substances which must be obtained pre-formed by the other) and antibiosis (for example, in the production of gramicidin, penicillin, or iodinin, which inhibit the growth of many other organisms).

A General Classification of Therapeutic Action

The present account has suggested a common basis for the actions of a wide range of substances in pharmacology and related sciences. This is amplified in the table opposite, which compares the activities of typical pharmacological and physiological agents such as eserine or phloridzin with acriflavine, microbial antibacterial agents, vitamins and hormones. The latter groups have an uncertain place in current text-books of pharmacology, though some authors have welcomed them as filling gaps in the 'materials of animal origin' left by extrusion of less delectable items of the older materia medica. Biochemical localization of drug action is in many cases still a subject for debate and research, and the types of action given cannot be exhaustive. The following points call for special comment.

(1) It is not intended to suggest that simple enzymic processes necessarily provide the basis for all therapeutic actions; obviously—as is suggested by Section V of the accompanying table—the presence of enzymes in cells is conditioned by other processes which may or may not be enzymic; also, the term 'enzyme system' has been used advisedly to include series of linked and dependent or physically associated reactions which may represent types of organization more complex than those of the typical purified enzymes, but which can be studied by biochemical methods in tissues and cells. In such studies *it is indeed especially necessary to consider the level* at which interaction with the biological component takes place[24].

(2) Enzyme reactions can be affected by means other than the supply of coenzyme or interaction with metabolite analogues, which have been emphasized in the above account; though the view has been expressed that most specific pharmacological actions are through structural resemblance between the active agents and natural substrates[25]. Certain natural antibacterial agents act through chemical reactions with enzyme or substrate: notatin[26] and milk flavoprotein[27] by hydrogen peroxide formation; penicillic acid, possibly by reaction with amino-acids[28]. These represent further types of action which make the metabolic processes of different organisms incompatible.

(3) The table presents a classification according to the systems upon which the drugs act. The present account has emphasized that in the case of naturally occurring agents this is one side only of a more complex interaction, and that to characterize fully such a drug it would be necessary to consider its relationship to systems in the organism of its origin. Synthetic drugs exhibit no such dual relationship. This provides one reason for the present classification according to the system affected by the drug. A second reason is that, *even among natural drugs, the occurrence of* many can be considered to be more related to the system which they affect than to that in which they originate, in so far as their perpetuation as defence mechanisms is accepted. The two aspects may be illustrated by, on one hand, snake venoms, which would appear to owe their present existence in snakes to their effect upon higher animals; on the other hand, it is more doubtful whether this is the case with toxins of bacteria the normal habitat of which is soil, as with *Clostridium tetani*.

With respect to synthetic drugs, the large number of compounds empirically prepared before a successful drug is discovered is only too evident; it has been generally realized, and expressed in the receptor theories, that this process was one of finding molecules to fit somewhat elusive structures in living cells. Such is the basis for the practice of using as guides almost any compound of natural occurrence, of

pharmacological action, or with the evident powers of combining with cells which are shown by certain dyestuffs. Greater knowledge of functioning systems in organisms can be expected to provide increasingly more direct methods of preparing compounds of desired activity; but it must be emphasized that the cinchona tree, for example, has had the experience of many millennia longer than humanity in dealing with organisms related to that causing malaria, and that the foregoing arguments suggest reasons for its having a shrewd initial measure of its opponent. For such reasons natural drugs can be expected to set high standards in their efficacy.

(4) It is inherent in the present thesis, and in the table, that an organism is a balanced system, the ordinary behaviour of which can be disturbed by either excess or deficiency of normal constituents or functions. Thus the promoting of an enzyme process by a drug, or any other of the actions I to V of the table, may result in either disturbance or readjustment of a system. When the system is the more complex one of chemotherapy, concerning host and parasite, the two processes are proceeding simultaneously in its different biological components. Though in this case the components can be relatively easily separated for experimental demonstration of the action of the drug upon each of them individually, agreement upon which is primarily affected by the drug has in many cases not yet been reached[29]. Comparable problems are encountered in the study of hormones and morphogenetic factors in higher organisms. It may be possible to suggest whether the primary action is one of stimulation or inhibition by the range of compounds producing given effects. It was found[22] that a much wider range of molecular type was compatible with substances acting as inhibitors than with their acting as promoters of reactions, and in explanation it was pointed out that in the first case it was requisite only for the substance, for example, to combine with an enzyme, while in the second case both combination and subsequent specific changes were necessary.

(5) Many drugs have more than one action, susceptible in some cases to differentiation at both pharmacological and biochemical levels. A given biochemical effect, however, would itself lead to varying pharmacological effects with varying location of the system affected. Chemotherapy, again, offers interesting examples in the actions of the sulphonamides, which by inhibiting a pathogen can prevent the production of, for example, hæmolysins and death of the host; but by inhibiting normal intestinal micro-organisms can *cause* nutritional deficiency and again a hæmatological disturbance in the host[30]. The actions have characters in common which suggest their biochemical identity. Such complexity emphasizes that considerations of the present type provide only one link, though the primary one, between the administration of a substance and the final therapeutic response.

CLASSIFICATION OF TYPES OF ACTION IN PHARMACOLOGY AND RELATED SCIENCES

Explanatory notes are given in square brackets; round brackets indicate that the allocation of the effect to a particular class is speculative.

Action through:		Examples in which the normal function of the subject is:	
		Restored or maintained	*Disturbed*
I. Promoting enzyme-processes	As coenzyme, or important part of it	Vitamins B_1, B_2; nicotinic acid (other vitamins[31] and trace-elements) [normal effects]; (non-protein hormones)	Vitamins [in hypervitaminoses]
	As enzyme	Intrinsic factor of pernicious anæmia; thrombin; angiotonase, renin[32]; (protein-hormones)	toxic plant proteases[42]; anti-B_1 factor of carp[43] [relation to fox and chick]. *Cl. welchii* toxin[44]; snake venom [relation to intoxicated animal].
II. Inhibiting enzymic or analogous processes	By combination as substrate, coenzyme, or analogue	sulphanilamide, pantoyltaurine[33] [overall effect in chemotherapy]; prostigmine, physostigmine[34]; (ephedrine, cocaine)[25,35]	sulphanilamide, pantoyltaurine[33] [effects on parasite in chemotherapy]; (avidin)[45]; CO; phloridzin.
	By other combination	acriflavine[36] [overall effect in chemotherapy]	acriflavine [effect on parasite] (phytic acid)
	Through biochemical action		guanidinoacetic acid[47]; alcohol[48] [some effects on other systems through lack of labile methyl groups and vitamin B_1]; notatin[26].
	Physical changes		narcotics [certain actions due to protein denaturation][37].
III. Removing inhibition of enzyme systems	Supplying coenzyme or substrate	*p*-aminobenzoate, pantothenate[33] [effects on parasite in chemotherapy with sulphanilamide and pantoyltaurine]	*p*-aminobenzoate, pantothenate[33] [effects on host in chemotherapy with sulphanilamide and pantoyltaurine].
	Physical changes	light [upon CO-inhibition of iron-porphyrin systems] pressure [upon narcotized bacteria][37]	
IV. By-passing enzyme systems	Supplying product of enzyme	p.a. factor of pernicious anæmia; oxaloacetate [to vitamin B_1-deficient organisms][38]	
	Supplying material simulating enzyme	methylene-blue, phenazine derivatives[36,39] [effects on parasite in chemotherapeutic interference]	methylene-blue, phenazine derivatives[39] [effect on host in chemotherapeutic interference]
V. Altering or destroying enzyme system or components		pantoyltaurine-resistance in *C. diphtheriæ*[40]; NaF-resistance in *Propionibact. pentosaceum*[41] (other drug resistance) [by biological reaction to environment]	some effects of heat[49] and irradiation[50] [direct effects of environment; restored by coenzymes or nutritional factors].

Conclusion

We have now the privilege of building upon the empirical findings of pre-scientific workers; upon the wholesome activities of those who swept pharmacy clear of magic and confusion; and upon the freshly gathered though still largely empirical results of the past fifty years. This paper has attempted to acknowledge our debt to each of these classes of investigator but in particular to connect the wider aspirations of the first with the experimental findings of the last of these groups. To earlier workers, who produced their effect by taking material from one organism and applying it to another, it was more apparent that connexions might exist between the origin of drugs and their actions. It was necessary to separate these two aspects for their initial scientific investigation, and views narrowed. An author, while giving as his aim the discovery of the laws of interaction between drugs and cells, limited himself to physico-chemical methods and interpretations; the study of drug-antagonism was divorced from the natural origin of the drug and the antagonist; text-books of chemotherapy were arranged according to the chemical structures of the agents. A conclusion supported by this paper is that for the understanding and theoretical presentation of pharmacology and chemotherapy, biochemistry and general biology are among the most immediately relevant sciences.

I am glad to acknowledge the advice received in discussing this subject with Drs. H. A. Krebs and A. Wilson of the University of Sheffield.

FUNDAMENTAL CONCEPTS OF NATURAL PHILOSOPHY

IN his recent James Scott Lecture, delivered before the Royal Society of Edinburgh, on "The Fundamental Concepts of Natural Philosophy" (*Proc. Roy. Soc. Edin.*, 62, Pt. 1, No. 2. Pp. 10–24. 1*s.* 3*d.*), Prof. E. A. Milne gave a comprehensive sketch of the theory of kinematical relativity which, with his collaborators, he has been developing during the last dozen years. The lecture contained no essentially new material, but it gave a very useful summary of the scope of the theory, with attention concentrated on the fundamental ideas, and its appearance marks a suitable occasion for forming an estimate of the significance of this new approach to the basic problems of natural philosophy.

The most fundamental concept of the scheme is that of the 'substratum', which is an idealized system of relatively moving particle observers, indefinitely numerous and each provided with a clock which he can graduate, in the first instance at pleasure. All such observers can send beams of light to the others and receive them back, by which means they become aware of the readings of the others' clocks, and they agree so to graduate their clocks that, for every pair of observers, A and B, "the totality of observations A makes on B coincide with the totality of observations B can make on A". They are then said to be "equivalent". Now suppose they wish to observe an external object. Each observer must (*a*) emit a beam of light at a time t_1 by his clock, and (*b*) observe his clock reading, t_2, at the instant at which he thereby observes the object. He must then form two specified independent functions of t_1 and t_2, involving the choice of a particular value for a conventional constant, c, and these functions he calls the *distance* and the *epoch*, respectively, of the object. Successive observations give a series of values of distance and epoch, and the relation between these constitutes the equation of motion of the object. The *law* of motion (or law of gravitation in the general case) is then determined by the condition that the totality of motions in the universe shall be described in the same way by all substratum observers; that is to say, if A observes an object at

distance r and epoch t as determined by his clock, B must also observe an object (not necessarily the same object) at distance r and epoch t as determined by *his* clock. "Gravitation", writes Prof. Milne, "is only the name given to the inevitable way in which particles must move in one another's presence and in the presence of the rest of the universe, if they are to move according to the same rules for all equivalent observers in the universe".

The function of the substratum is thus to provide a stage for the display of natural motions; it corresponds in this theory to Euclidean space in ordinary geometry or to space-time in Minkowskian kinematics. It is not something which actually exists in the naïve sense of the phrase, but a conception which serves to determine the form in which observations of actually existing bodies shall be tabulated, and to define the sphere of possibility of actually occurring motions. "The theoretical, the ideal, the abstract substratum", writes Prof. Milne, "this system of moving particles, monads, observers . . . possesses a great many strange and surprising properties. . . . Just as the Euclidean plane is the stage, the scene, the background against which the phenomena of geometry—its figures and its theorems—display themselves, so the substratum is the background against which the phenomena of dynamics and gravitation display themselves".

Against this background, then, the actual bodies of the universe are to be contemplated and their behaviour observed, and here we encounter an ambiguity which I have invariably felt in reading Prof. Milne on this subject, and which remains unresolved here. Just as the Euclidean character of space tells us nothing about the number or distribution at any moment of the objects observable in space, so one would expect that the characteristics of the theoretical, ideal, abstract substratum would tell us nothing about the number or distribution of practical, real, concrete objects which present themselves for description in terms of it. This, however, appears not to be so. The behaviour of a free particle is determined not only by the demands of the observers in the substratum, but by the "rest of the universe"—that is, all the other concrete particles—also: and, furthermore, the "rest of the universe" is controlled, in both content and behaviour, by the condition that the substratum observers shall give the same general description of the whole. When one asks the reason for this, however, the answer is puzzling. We cannot deduce the motion of a single free particle without considering the rest of the universe, says Prof. Milne, for "if we are asked what is the motion of a free particle in 'empty space', *i.e.* in the presence of one observer alone, the question is an illegitimate one, and we cannot answer it". But we do not ask what is the motion of a free particle in the presence of one observer alone, but what is the motion of a single concrete particle in the presence of all the ideal substratum observers, and no reason is given why we cannot state it. We can only assume that the universe cannot contain only a single particle, because if so the substratum observers could not give the same account of it; but it would have been more satisfactory if this had been plainly stated.

The theory proceeds to deduce the way in which the universe must be populated with concrete bodies, and how those bodies must move in one another's presence, in order that it shall conform to the requirements of the substratum. This, of course, involves much mathematics, of which the chief conclusions are given in the lecture, and we reach a point at which the resulting "law of gravitation" can be compared with the familiar Newtonian law. The classical "constant of gravitation" turns out to be a function of time, but it can be made to "masquerade as a constant" by a transformation of the time-scale to that used by Newton. The deductions of the theory, however, are at present of less interest than the foundations, and we turn to an examination of the fundamental postulates.

It must be admitted that Prof. Milne speaks no more than the truth when he describes the substratum as possessing strange and surprising properties. We have become accustomed to 'spaces' which turn back on themselves and do other queer things, and it is an axiom of general relativity that the properties of space vary with its material content—that space, in fact, is less aptly described as a frame into which bodies must fit than as a garment shaped to their figure. But of all previous thinkers who have taken liberties with space, none, so far as I know, has given it intelligence. The substratum, however, is *essentially* intelligent. Each particle of it is necessarily accompanied by an observer—*is*, in fact, an observer, since it has no function but that of observing, recording and calculating. "Observers are an essential element in the situation", writes Prof. Milne. Nor is "observer" here merely a picturesque term for "observing instrument", as in the popular accounts of Einstein's relativity. The substratum observers must not only record the pointer-readings of clocks; *they must also agree to give the same value to a conventional constant, c*, otherwise their readings are useless. This cannot be done without communication by means of an agreed conventional language, and for this minds, and not merely instruments, are essential. We cannot escape from this, nor, apparently, does Prof. Milne wish to do so, for he states as one of his two principal motives throughout the work, "the attempt to say exactly what is meant by a quantitative statement in terms of operations that could be actually carried out, and communicated to a distant observer elsewhere in the universe, who could repeat similar observations, on these instructions, himself".

Parenthetically, it is worth while to point out a common misunderstanding, which Prof. Milne seems to share, concerning the meaning of 'observer' in Einstein's theory of relativity. It is often said that the purpose of the theory is to reconcile observations of observers in relative motion. That is a mistake, arising from a well-meant but unfortunate device widely adopted for explaining the theory in an attractive way. What the theory actually does is to prescribe how a single observer must change his measure numbers when he changes his co-ordinate system; for example, when (absolute motion having no significance) he changes his arbitrary standard of rest from one body to another. As a theory based on experience it can obviously do no more, for we have measurements of only one observer—a terrestrial one. The Michelson-Morley experiment did not compare observations by terrestrial and solar observers. It showed that the single result obtained by a single observer was to be expected, no matter whether that observer regarded himself as at rest or as moving round the sun. Of course, we can deduce what the theory would require a solar observer to measure if he used the same kinds of instruments and the same rules of calculation as ourselves, and the

deduction, like any other, might turn out to be incorrect if we ever succeeded in observing a terrestrial experiment from the sun. In that case the theory would have to be revised. The essential point is that hypothetical observers play no part in the theory *per se*. Anything we may say about them has the character of a scientific romance.

If the substratum postulate referred to above were shown to issue in the actual laws exhibited by moving bodies, and to form a simpler axiomatic basis than any other so far devised, it would have to be given serious attention. We might try to reformulate it so as to bring it more into line with general physical convention, but if we failed to do so, no plea of apparent absurdity would justify its rejection. We have learnt—or should have learnt—by now that nothing is too fantastic (that is, contrary to expectation) to be true. But this would not at all win Prof. Milne's approval, for it would subject the postulate to the test of *experience*, and its significance to him is that its validity is *beyond* experience; the postulate is advanced as self-evident and inevitable. The other of his two principal motives already mentioned is "the desire never to introduce, unsuspectedly, any elements of *contingent* law". He proposes in his lecture to show how "we are led to quantitative laws relating phenomena in the external world which are *inevitable* [my italics] relations between the elements of perception". "The more advanced a branch of science", he writes, "the more it relies on inference and the fewer the independent appeals to experience it contains. . . . The question arises as to whether this process of inferring can come to a stop, and if so, where. Is there an irreducible number of brute facts derived from observation? . . . The answer seems to me to be that we can reduce the appeals to *quantitative* experience to zero".
